Combined deep inferior epigastric perforator flap with a high-density polyethylene patch for reconstruction of complex chest wall defects: A case report

Shengchao Huang, Chunyan Chen, Pu Qiu, Zeming Yan, Weizhang Chen, Zhongzheng Liang, Kangwei Luo, Jianwen Li, Yuanqi Zhang, Baoyi Huang
Abstract

BACKGROUND

Chronic radiative chest wall ulcers are common in patients undergoing radiation therapy. If not treated early, then symptoms such as erosion, bleeding and infection will appear on the skin. In severe cases, ulcers invade the ribs and pleura, presenting a mortality risk. Small ulcers can be repaired with pedicle flaps. Because radioactive ulcers often invade the thorax, surgeons need to remove large areas of skin and muscle, and sometimes ribs. Repairing large chest wall defects are a challenge for surgeons.

CASE SUMMARY

A 74-year-old female patient was admitted to our department with chest wall skin ulceration after radiation therapy for left breast cancer. The patient was diagnosed with chronic radioactive ulceration. After multidisciplinary discussion, the authors performed expansive resection of the chest wall ulcers and repaired large chest wall defects using a deep inferior epigastric perforator flap combined with a high-density polyethylene patch. The patient was followed-up 6 mo after the operation. No pigmentation or edema was found in the flap. +ACYnbsp+ADsAPA-/p+AD4APA-/html+AD4-

CONCLUSION

Deep inferior epigastric perforator flap plus high-density polyethylene patch is one of the better treatments for radiation-induced chest wall ulcers.

Key Words: Deep inferior epigastric perforator flap; High-density polyethylene patch; Breast cancer; Chest wall; Chronic radiation-induced ulcer; Case report

Core Tip: In recent years, with the development of microsurgical techniques and breast reconstruction techniques and the wide application of autologous flap transplantation, breast surgeons have provided new ideas for the treatment of chronic radiation-induced ulcers of the chest wall. Deep inferior epigastric perforator flap combined with a high-density polyethylene patch is a promising treatment for chronic radiation-induced ulcers of the chest wall.

INTRODUCTION

The incidence of chest wall ulcers due to chronic radiation is about 25%-30%. The radiation dose, radiation time and patient’s condition are the risk factors known to affect its occurrence. It has been reported that radiation doses exceeding 70 Gy/7 wk/30 fractions are prone to cause such ulcers[1]. Radiation-induced ulcers of the chest wall are secondary, progressive and irreversible, with a duration of as short as several months and as long as years or decades. Moreover, they can be classified as a special type of protracted wound. In addition, radiation can cause vascular contracture, reduce the amount of blood supplied to the skin, induce fibrosis of the skin, and directly impair the repair function of the skin tissue[2-5]. Chronic radiation-induced ulcers of the chest wall are often associated with infection and easily cause rib necrosis and osteomyelitis. This seriously affects the quality of life of patients and is a detriment to a patient’s confidence in treating cancer. In the past, surgeons have tried to treat it with debridement and dressing change or skin grafting, but it is difficult to achieve the ideal therapeutic effect.

At present, chest wall reconstruction includes two parts: bone reconstruction of the chest wall, and soft tissue reconstruction of the chest wall. The former uses biological or artificial materials to restore stability of the chest wall, while the latter realizes the tightness of the chest wall by transferring its own tissue flap to cover the defect. In the repair of the chest wall, titanium alloy plates and high-density polyethylene (HDPE) patches are two commonly used materials. Some scholars have pointed out that HDPE
patches have sufficient toughness and can better maintain the stability of the chest wall without interference with radiotherapy\[6\]. In terms of soft tissue repair, a banded myocutaneous flap is better to repair chest wall defects; however, the excessive muscle harvested during the surgery causes the patient sustains greater trauma, resulting in prolonged recovery time and affecting the subsequent treatment of patients. Due to the development of microsurgical techniques, the application of free flaps to repair chest wall defects has become a clinical hot spot. In this report, the breast cancer patient suffered from a chronic radiation-induced ulcer of the chest wall combined with necrosis of the second to fifth ribs. The chest wall defect was repaired by deep inferior epigastric perforator (DIEP) flap combined with a HDPE patch, with good postoperative recovery.

**CASE PRESENTATION**

*Chief complaints*

A 74-year-old female patient was admitted for a radioactive ulcer on the chest wall for more than 4 mo.

*History of present illness*

The patient’s chest wall ulcer occurred 1 wk after the 6th radiotherapy treatment and lasted about 4 mo. The area of the ulcer was 4 cm × 6 cm. The surface of the ulcer was dirty, and the basal granulation tissue was sparse. The ulcer surface bled easily, which indicated that it was closely attached to deep tissue. The ulcer was hard and surrounded by scar tissue.

*History of past illness*

The patient underwent modified radical mastectomy of the left breast in our department 5 mo prior. The patient did not have hypertension, diabetes or hyperlipidemia.
**Personal and family history**

Personal and family history was unremarkable.

**Physical examination**

An irregularly shaped ulcer was observed on the surface of the skin of the left chest wall and measuring 4 cm × 6 cm. It was accompanied by red coloration, fishy odor, and pus-like discharge. The skin around the ulcer was red and swollen, hard in consistency and tender (Figure 1). No significantly enlarged lymph nodes were palpable in the left axilla or supraclavicular region.

**Laboratory examinations**

All laboratory tests were normal.

**Imaging examinations**

Chest computed tomography: Irregular subcutaneous soft tissue of the left anterior chest wall and multiple small nodular high-density shadows in the local area were observed. These were predicted to change after radiotherapy. Slightly disordered structure of the left axilla was also observed but no enlarged lymph nodes were found.

**MULTIDISCIPLINARY EXPERT CONSULTATION**

The consultation included specialists in breast surgery, thoracic surgery and radiology. After discussion by several specialists, the decision was made to perform an expanded excision of the ulcer on the chest wall of the patient, including the invaded muscle and ribs. Then, the thoracic defect would be repaired with a patch, and the chest wall defect would be covered with a free flap (Figure 2).

**FINAL DIAGNOSIS**

Radiation-induced ulcer of the left chest wall (Figure 3).
**TREATMENT**

DIEP flap combined with an HDPE patch was used to repair the chest wall ulcer.

**OUTCOME AND FOLLOW-UP**

The patient was followed-up for 6 mo after the operation. The skin flap showed no pigmentation and no edema. The skin growth and healing of the donor site were acceptable. The donor site was not complicated with abdominal skin necrosis, abdominal bulge, abdominal weakness, nor abdominal hernia.

**DISCUSSION**

Although radiotherapy equipment, technology and design have been developed to varying degrees in recent years, the occurrence of chronic radiation-induced ulcers of the chest wall are still common when radiation therapy is received after breast cancer surgery.

According to scholars, conservative treatment of radiation-induced ulcers using debridement, dressing change and antibiotics is ineffective for most patients[7]. Many clinicians have tried different methods to treat chronic radiation-induced ulcers of the chest wall. According to Nishimoto *et al*[8], an ideal therapeutic effect was observed in 4 patients upon transfusing platelet-rich plasma and simultaneous skin grafting. Other studies have reported that chronic radiation-induced ulcers of the chest wall have been cured by intravenous infusion of plasma-purified mannann-binding lectin to patients[9,10]. Researchers have also conducted an animal experiment (in guinea pigs) and administered arginine glutamate after artificially causing radiation-induced ulcers, and the therapeutic effect of the ulcers was adequate[10,11]. However, due to individual differences, the above treatment has not been widely promoted in clinical practice, and surgical treatment is still the main treatment. Radiation injury causes soft tissue damage and leads to necrosis of the sternum and ribs. Surgical reconstruction of the chest wall includes two parts: thoracic reconstruction and soft tissue repair. It is generally believed that if the anterolateral chest wall defect is
less than 6 cm × 6 cm and the posterior chest wall defect is less than 10 cm × 10 cm, then generally no thoracic reconstruction is required\[10,12]\). Soft tissue coverage alone can eliminate the abnormal respiratory movement of the chest wall after surgery. However, large defects require thoracic reconstruction to restore the firmness and stability of the thorax in order to protect the viscera and maintain normal respiration. In the reconstruction of the bony chest wall, two kinds of synthetic materials — titanium alloy plates and HDPE soft patch — are mostly used. HDPE patches have good toughness and elicit minimal aseptic inflammatory response. In a short time, human tissue can grow on the patch and cover the cavity in the body, which is conducive to wound repair. In addition, the patch is easy to cut and use during surgery. However, compared with a titanium alloy plate, its hardness and support force are not satisfactory. Occasionally, when the patient breathes, the HDPE patch suture loosens, which results in deformation of the chest wall. However, HDPE patches do not interfere with subsequent radiation therapy.

Thorough debridement and myocutaneous flap coverage of the defect are the preferred methods for the surgical treatment of chest wall ulcers. When debridement of thoracic ulcers is performed, it is required to remove the injured skin and subcutaneous soft tissue, necrotic ribs, sternum, clavicle and surrounding muscle fibrous tissue as much as possible. The choice of myocutaneous flaps, such as latissimus dorsi flap, pectoralis major flap and rectus abdominis flap, is preferred\[6\]. These myocutaneous flaps have the advantages of rich tissue volume, stable vascular pedicle course, and easy operation. However, due to the harvesting of a large amount of autologous muscles from patients, they cause greater trauma to individuals and result in a longer recovery time, which may delay the subsequent treatment time. In contrast, pedicle musculocutaneous flaps are difficult to cover large wounds due to their small incision area. In this case, DIEP soft tissue was used to repair the chest wall defect. Without harvesting the muscle, there was a sufficient amount of tissue to cover the defect, which was less invasive to the patient and had less recovery time, that did not disrupt subsequent radiotherapy. However, compared with other myocutaneous flaps, DIEP
has a relatively small amount of tissue and cannot be used to cover deeper or larger defects. Moreover, the operation of DIEP is relatively complex and requires knowledge and expertise in microvascular anastomosis surgery, which is difficult to promote in clinical practice.

The main characteristics of this case were: (1) Intraoperative use of DIEP does not cut the rectus abdominis muscle, making it less invasive to the patient and shortening the postoperative recovery time; and (2) Intraoperative use of HDPE patches can maintain stability of the chest wall and does not interfere with the patient’s subsequent radiotherapy.

CONCLUSION

In summary, for patients with smaller chest wall defects accompanied by rib necrosis, DIEP combined with HDPE patch repair can be used to obtain satisfactory clinical efficacy and reduce the occurrence of postoperative complications. This may be a better way to treat large chest wall radiation-induced ulcers.
