Portal vein gas combined with pneumatosis intestinalis and emphysematous cystitis: A case report and literature review

Hu SF *et al.* PVG combined with PI and EC

Shi-Fu Hu, Han-Bo Liu, Yuan-Yuan Hao

Abstract

BACKGROUND

Portal venous gas (PVG) is a rare clinical condition usually indicative of severe disorders, including necrotizing enterocolitis, bowel ischemia, or bowel wall rupture/infarction. Pneumatosis intestinalis (PI) is a rare illness characterized by an infiltration of gas into the intestinal wall. Emphysematous cystitis (EC) is relatively rare and characterized by intramural and/or intraluminal bladder gas best depicted by cross-sectional imaging. Our study reports a rare case coexistence of PVG presenting with PI and EC.

CASE SUMMARY

An 86-year-old woman was admitted to the Emergency Department due to the progressive aggravation of pain because of the abdominal fullness and distention, complicated with vomiting and stopping defecation for 4 d. The abdominal computed tomography (CT) plain scan indicated intestinal obstruction with ischemia changes, gas occurring in the portal vein, left renal artery, superior mesenteric artery, superior mesenteric vein, and some branch vessels, and bladder pneumatosis with air-fluid levels. Emergency surgery was conducted on the patient. Ischemic necrosis was found
in the small intestine approximately 110 cm below the Treitz ligament, as well as in the ileocecal junction and ascending colon canals. This included excision of the necrotic small intestine and right colon, fistulation of the proximal small intestine, and distal closure of the transverse colon. Subsequently, the patient displayed postoperative short bowel syndrome but had a good recovery. She received intravenous fluid infusion and enteral nutrition maintenance every other day after discharge in the community hospital.

CONCLUSION

Emergency surgery should be performed when CT shows signs of PVG with PI and EC along with a clinical situation strongly suggestive of bowel ischemia.

**Key Words:** Portal vein gas; Mesenteric ischemia; Pneumatosis intestinalis; Emphysematous cystitis; Bowel necrosis; Case report

**Core Tip:** Portal venous gas (PVG) caused by intestinal necrosis is a severe condition requiring surgery. PVG with superior mesenteric vessels gas, pneumatosis intestinalis (PI), and emphysematous cystitis (EC) reflect different stages of the same pathophysiological disorder. The specificity of PVG, PI, and mesenteric vein gas to computed tomography diagnosis of acute intestinal ischemia is nearly 100%. The coexistence of PVG, PI, and mesenteric venous gas can be an important diagnostic marker for acute ischemic bowel disease. When intestinal ischemia or necrosis is suspected, active surgical exploration should be the first line of treatment. It is really rare for PVG complicated with superior mesenteric vessels gas, PI, and EC.
INTRODUCTION
Portal venous gas (PVG) is a rare accumulation of gas in the portal vein system (from the superior mesenteric vein and its branches to the liver). Clinically, PVG is considered to be one of the non-specific signs in major abdominal diseases rather than a specific disease entity. There are more and more cases of PVG with the wide application of computed tomography (CT). However, it is exceptionally unusual for PVG complicated with superior mesenteric vessels gas, pneumatosis intestinalis (PI), and emphysematous cystitis (EC). Therefore, we describe the diagnosis and treatment of this case.

CASE PRESENTATION

Chief complaints
Due to abdominal pain and distension, an elderly woman went to the emergency room in the hospital.

History of present illness
Due to the abdominal fullness and distention, she suffered from the progressive aggravation of pain, complicated with vomiting and stopping defecation for 4 d.

History of past illness
Medical history consists of coronary heart disease, atrial flutter, hypertension, Type 2 diabetes, and chronic renal insufficiency.

Personal and family history
None.

Physical examination
The body temperature was recorded to be 36.7 °C, heart rate 108/min, respiratory rate 22/min, and blood pressure 110/68 mmHg. The clinical examination presented the symptoms like indifference, slow response, painful appearance, abdominal fullness and
distension, scattered tenderness and mild rebound tenderness, no obvious muscle
tension, with drum sound and borborygmus disappeared when performing percussion.

**Laboratory examinations**
The examination outcomes of WBCs are normal, with hemoglobin 80 g/L; RBC count
2.95 × 10⁹/L; platelet count 123 × 10⁹/L; Neutrophil proportion 82.8%; and CRP > 320
mg/L; PT 17 s; APTT 48.6 s; FIB 7.44 g/L and D-dimer 5920 μg/mL; PCT 19.75 ng/mL;
ALB 28.6 g/L; serum creatinine 186.3 μmol/L; BNP 347.26 pg/mL and Mb 698.1
ng/mL; CTnI 0.1 ng/mL; and her electrocardiogram showed atrial flutter.

**Imaging examinations**
According to the abdominal ultrasound examination, intrahepatic blood vessels were
extensively pneumatized, the gallbladder wall was not smooth, and had calculi. Cardiac
ultrasound examination showed enlarged left atrium and thickened aortic ventricle
with pericardial effusion (7 mm). As per the chest CT examination, pericardial effusion,
lungs texture was increased, with a little shadow in the lower lobe of the left lung,
which may be caused by inflammation. Abdominal CT plain scan showed abdominal
free-air, ascites, the dilated small intestine lumen with gas and effusion scattered signs
in air-fluid level, and there were multiple gas density shadows between the intestinal
walls, which was consistent with intestinal obstruction and intestinal ischemia changes
(Figure 1A). Multiple dendritic gas density shadows were visible in the liver and liquid
density shadows around the liver (Figure 1B). Gas occurs in the portal vein, left renal
artery, superior mesenteric artery, superior mesenteric vein, and some branch vessels
(Figure 1C). Figure 1D shows bladder pneumatosis complicated with air-fluid levels.
Figure 1E shows histopathological examination of surgical specimens confirmed the
changes caused by mesenteric ischemia.

Upon microscopic examination, the patient did have coagulation necrosis of some
small intestinal colon mucosa, erosion with ulceration, muscle degeneration like a
honeycomb, hematoma formation in the submucosa, and thrombosis in the blood
vessels, all of which may be caused by ischemic bowel disease. Congestion occurred in the vessel inside the omentum, with thrombosis in hemorrhage (Figure 2).

**FINAL DIAGNOSIS**

The final diagnosis of the case was intestinal obstruction, intestinal necrosis, portal vein gas, superior mesenteric vessels gas, pneumatosi s intestinalis, emphysematous cystitis, and acute mesenteric ischemia. Mesenteric vessels gas, pneumatosi s intestinalis, emphysematous cystitis, and acute mesenteric ischemia.

**TREATMENT**

During an emergency laparotomy, 500 mL of purulent ascites were found in the abdominal cavity. The section from the small intestine about 110 cm below the Treitz ligament to the remaining whole small intestine and ileocecal junction, as well as the intestinal canal of ascending colon, was dilated. The intestinal wall was gray and stiff, displaying "spot"-like ischemic necrosis, obvious edema, and no peristalsis. Snow-holding sensation and thrombosis within mesenteric vessels can be felt when the diseased intestinal canal is squeezed. Therefore, these surgical procedures were performed, including necrotic small intestine and right colon excision, proximal small intestine fistulation, and distal transverse colon closure.

**OUTCOME AND FOLLOW-UP**

Following anti-infection, supportive transfusions of RBCs and platelets, crystalloid rehydration, and nutritional support were administered; the patient’s postoperative recovery was uneventful. In a step-like manner, infection indicators decreased to nearly normal levels. There were no noteworthy abnormalities in abdominal signs. On the eighth postoperative day, an abdominal CT plain scan presented gas in the portal vein, left renal artery, superior mesenteric artery, superior mesenteric vein, intestinal wall, and bladder was entirely absorbed (Figure 3A-C). The diet has returned to normal. Urine was normal, the water-like stool was smoothly drained from the stoma, and the
amount was slightly large. We performed the support treatment of enteral nutrition with intravenous water and electrolyte supplement of 1000 to 1500 mL/d in the presence of oliguria and aggravation of renal insufficiency caused by short bowel syndrome. The patient was discharged on the 37th postoperative day. Afterward, she received intravenous fluid infusion and enteral nutrition maintenance every other day in the community hospital.

**DISCUSSION**

PVG is a relatively rare imaging manifestation in a clinic that refers to an abnormal accumulation of gas in the portal vein and its branches due to various reasons. The portal vein trunk is formed by the superior mesenteric vein and the splenic vein, which after entering the liver, divides into left and right branches of the portal vein. As per the report by Wolfe and Evens, gas can accumulate in intrahepatic portal vein branches or and extrahepatic portal vein trunk and mesenteric vein in abdominal X-rays of newborns with necrotizing enterocolitis[1]. With the advancement of imaging technology, people progressively realize that PVG is not a disease and cannot be used as a predictor of death alone; however, it may be severe and complicated iatrogenic or non-iatrogenic manifestations of abdominal infection, abdominal trauma, mesenteric ischemia, diverticulitis, gastrointestinal diseases, and gastric ulcer, or the difficulties of duodenal perforation, diving, accidental intake of hydrogen peroxide with high concentration, and endoscopic surgery[2-5].

PVG is caused by three main pathophysiological mechanisms: (1) gastrointestinal mucosal injury that makes gas in the gastrointestinal cavity enter mesenteric portal vein system through the injured site or mucosa with increased permeability, such as intestinal ischemia, endoscopic examination, and operation; (2) the gastrointestinal lumen is dilated, the pressure in the intestinal lumen increases, and edema or even ischemic necrosis may occur in some intestinal canals, which makes the lumen gas enter the portal vein system, such as trauma or intestinal obstruction; (3) bacterial theory indicates that on the one hand, gas-producing bacteria invade submucosa to produce
gas, which is absorbed by the submucosal blood vessels, and on the other hand, bacteria directly invade blood to form septicemia or phlebitis to produce gas, etc.[6].

PI is also a rare pathology, with a global incidence of 0.03% and a threefold increase in males[7-10]. It is also a common radiological sign, with over 60 different causes[11]. PI can be primary or secondary to other diseases, with the latter accounting for 85% of cases. These other diseases include abdominal trauma, intestinal obstruction, inflammatory bowel disease, malignant tumor, chemoradiotherapy, chronic lung diseases, and connective tissue diseases[12-14]. However, the mechanism by which gas enters the intestinal wall is unknown. To explain this mechanism, several hypotheses have been proposed, such as the pulmonary, mechanical, and bacterial hypotheses[15]. According to pulmonary theory, chronic lung diseases like COPD and asthma can rupture alveoli, causing mediastinal emphysema and trapping gas in the intestinal wall via the aorta and mesenteric vessels. The mechanical theory of cyst formation refers to increased intraluminal pressure caused by intestinal obstruction or other diseases that can cause mucosal damage and cyst formation. The bacterial theory refers to intestinal bacteria that produce gas and trap it in the submucosa[16], as opposed to aerogenic bacteria that directly penetrate the intestinal mucosa and produce gas[17]. PI is sometimes an incidental finding, but it can foreshadow a life-threatening intraabdominal condition in some clinical settings, particularly in the presence of peritonitis, metabolic acidosis, and portal venous gas[18]. The treatment chosen is determined by the complications and underlying causes of PI. For individuals with visible manifestations of PI, conservative treatments such as oxygen therapy, antibiotics, and parenteral nutrition are recommended[19]. We did not perform a colonoscopy because the patient had symptoms of peritonitis and apathy, and CT indicated that the diseased bowel was concentrated in the small intestine. However, surgical treatment is recommended if the patient has surgical complications such as intestinal obstruction, intestinal perforation, bleeding, intestinal ischemia and necrosis, or the presence of gas in the portal vein[20-22].

It is particularly rare that PVG and mesenteric vein and intestinal pneumatosis occur, with the occurrence rates of 3%-14% and 6%-28%, respectively, which is a characteristic
manifestation of acute intestinal ischemia\textsuperscript{[23]}. In cases of intestinal ischemia, there are
two processes for the production of PI. One is ischemic necrosis of the intestinal wall
mucosa, and the other is mechanical damage of the intestinal wall mucosa that can
cause gas in the intestinal lumen to enter the intestinal wall or (and) bacteria to invade
the intestinal wall to create gas for repeated infection. PVG and PI reportedly represent
different stages of the same pathophysiological condition\textsuperscript{[24]}. PVG is generated using the
same method as PI, and gas in the intestinal wall further enters the portal vein system
without a venous valve through the intestinal wall venules and lymphatic vessels\textsuperscript{[25]},
The gas shadow can spread all over the left and right branches and trunk of the portal
vein and even invade the superior mesenteric vein in individuals with severe disease\textsuperscript{[26]}. The incidence of PVG related to PI is generally caused by intestinal ischemia. PVG
related to PI is a severe disease and is related to poor prognosis\textsuperscript{[27,28]}. Among them,
intestinal necrosis is the most common cause of mortality in adult PVG patients (43\%-
75\%). PVG, complicated with intestinal ischemia or necrosis, indicates a poor prognosis.
Furthermore, the severity of PVG is also associated with basic diseases, and life risks
may occur in patients with serious diseases\textsuperscript{[29]}. As a result, Matsuoka \textit{et al}\textsuperscript{[30]} noted that
intestinal necrosis had occurred in many cases in diagnosis, and the infarcted intestinal
segment needed to be removed. Recently, Koizumi \textit{et al}\textsuperscript{[31]} through statistical analysis of
Japan's hospitalization database, found that 53\% of PVG patients have potential
intestinal ischemic diseases, while the hospitalization mortality rate is 27.3\%, 32\% of
patients have received surgical treatment, and the mortality rate has significantly
decreased, similar to the results of García-Moreno \textit{et al}\textsuperscript{[32]}. Hence, intestinal ischemia or
necrosis is still an important cause of PVG.

EC is defined by the accumulation of air inside the bladder wall and/or lumen. It is
one of the uncommon varieties of a urinary tract infection due to gas-producing
bacteria. With a mortality rate of 7.4\%, EC is a rare but critical condition\textsuperscript{[33]}. It is
commonly seen in elderly, diabetic females with an infective organism\textsuperscript{[33]} and in
immunocompromised people\textsuperscript{[34-36]}. Very little information regarding emphysematous
cystitis has been reported. Pathogens associated with this condition include gas-forming bacteria such as *Escherichia coli, Klebsiella pneumoniae,* and *Enterococcus*.[37,38]

In this scenario, the patient is elderly, and there are many risk factors of mesenteric ischemia in the past medical history, such as coronary heart disease, atrial flutter, atherosclerosis, diabetes, and chronic kidney diseases. The onset process is marked by an acute attack, with severe symptoms and non-obvious indicators in the early stages, followed by increasing aggravation in the later stages. There was no positive indication in the initial examination that made it difficult to confirm the diagnosis accurately. However, as the disease progressed, the patient developed symptoms of peritonitis and apathy, a potentially fatal infectious presentation in the elderly. Her condition did not improve when a high flow of oxygen was administered early in her hospitalization. The examination results showed Neutrophil proportion 82.8%, CRP > 320 mg/L, and PCT 19.75 ng/mL, which showed that there was a bacterial infection in the patient. D-dimer: 5920 µg/mL; which is more than ten times higher than the normal value, representing the risk of thrombosis; CT image indicated that abdominal free-air, ascites, PVG, superior mesenteric arteriovenous (SMA) gas, PI and EC coexist. These results are strongly suggestive of mesenteric ischemia. Previous research has shown that PVG, PI, and CT have a 100% sensitivity to detect acute intestinal ischemia.[23]. Although intramural gas and portal venous gas are frequently discovered. Gas in the SMA is extremely rare, but it is critical for detecting severe mesenteric ischemia.[39,40]. Only two cases were found in the literature; one patient had diffuse intestinal necrosis with SMA occlusion, and the other patient had acute aortic dissection with intestinal necrosis. Non-surgical patients with ascites (by CT), peritoneal irritation (by physical examination), and shock (by checking vital signs) are thought to be in life-threatening conditions.[41]. It appears to be appropriate as a convenient laparotomy decision criteria. Based on the above results, it shall not preclude the combined action of the strangulated intestinal obstruction caused by esenteric arterial (for the abdominal small intestinal blood supply) embolism due to thrombus from coronary heart disease, atrial flutter, atrial fibrillation, atherosclerosis, and other cardiovascular diseases, the higher
intestinal lumen pressure, intestinal mucosal layer edema or necrosis, and destroyed mucosal barrier, initiating intestinal lumen gas to penetrate into the intestinal wall venules and flow back to the portal vein through mesenteric vessels, in the meantime, intestinal and abdominal gas-producing bacterial infection disturbing intestinal mucosal venules, and the direct infection of intravenous gas-producing bacterial\[42\]. In patients, however, changes in superior mesenteric artery gas, left renal artery gas, and EC can be explained by gas infiltration into the intestinal lumen after intestinal canal ischemia and direct infection with aerogenic bacteria, which is yet to be definitively proven. This may be related to E. coli, which is the most common cause of EC\[43\].

Through well-timed emergency surgical exploration, it was established that the range of the necrotic intestinal canal was consistent with the changes of ischemic region after superior mesenteric artery embolization. During the operation, the corresponding intestinal segment and mesentery were removed to save the patient’s life. According to previous literature\[18\], that PVG generally indicates intestinal wall ischemia and necrosis, which is often the late sign of intestinal wall ischemic necrosis, but PVG has no sign effect on the severity of intestinal wall ischemic necrosis. Liebman et al\[44,45\] reported that PVG is an evident indication of surgical exploration in the acute abdomen. PVG, however, is not an absolute indication for emergency surgery, as more studies have revealed its presence in the development of various diseases\[2-5\].

Although surgical removal of the damaged portion was previously thought to be the only effective therapy, advanced imaging modalities such as CT have shown that some patients can recover with non-surgical, conservative treatments\[44,46-49\]. PVG was mostly not associated with intestinal necrosis in the patients who recovered, implying that not all PVG patients require surgery\[49\]. However, the patient had peritonitis and apathy, and the presence of PI, PVG, and mesenteric venous gas is a strong indicator of acute ischemic bowel disease. Cases of PI and PVG with benign etiology have been reported infrequently in the literature\[28\]. The presence of both almost always indicates mesenteric infarction and bowel necrosis\[50\]. This has a poor prognosis, with mortality rates ranging from 39% to 80%\[24,50\], and in some series approaching 100%\[50\]. Imaging
alone makes it difficult to distinguish between benign and life-threatening causes\cite{2}. Instead, the clinical picture and laboratory findings of the patient should guide this decision. Thus, we believe that caring clinicians should base their decision to operate on the patient's clinical state, particularly any signs of peritonitis and other laboratory adjuncts. Most studies agree that exploratory laparotomy or laparoscopy is justified when in doubt and in patients who can tolerate surgery\cite{24,50}. Diagnostic laparoscopy, which is less invasive, should be considered first if the clinical situation allows. However, if the patient is diagnosed with mesenteric infarction and intestinal necrosis via laparoscopy, a complete abdominal laparotomy is still recommended. Especially, active surgical exploration is the first-line treatment for intestinal necrosis when ischemia or necrosis is suspected\cite{48}. The treatment given to this patient is consistent with Piton et al\cite{51} report. In order to avoid the deterioration of disease for intestinal necrosis, these ischemic intestinal canals should be actively removed during the operation. However, in the absence of ischemia of the intestinal wall, conservative treatments and close observation must be followed.

The clinical treatment of PVG must be provided as per the etiology. Nelson\cite{48} outlined the "ABC" grading treatment principle for clinical treatment of PVG: (1) If the onset of the disease is urgent and the clinical symptoms are severe, and CT displays signs of intestinal ischemia and intestinal necrosis, the mortality rate of such patients can reach 75\%, which should be dynamically treated and emergency laparotomy should be carried out; (2) If the onset of the disease is relatively slow and the clinical symptoms are comparatively mild, the mortality rate of such patients is between 20\% and 30\%, which could be closely observed initially, and provided with surgical treatment if necessary; (3) If there is only PVG without emergency or only PVG after the operation, conservative treatment such as fasting and gastrointestinal decompression can be provided.

**CONCLUSION**
We study the diagnosis and treatment of this patient with PVG, secondary to changes of mesenteric ischemia, complicated with superior mesenteric vessels gas, PI, and EC. Therefore, once the PVG, complicated with PII and mesenteric vein gas, is found in CT examination, we must thoroughly investigate the causes of various factors and give priority to mesenteric ischemia and related diseases. Once emergency treatment is needed, we should actively find the etiology and carefully determine a treatment scheme.
