Retrospective Study
Chicken skin mucosa surrounding small colorectal cancer could be an endoscopic predictive marker of submucosal invasion

Zhang Y et al. Early invasion signs in colorectal cancer

Ying-Jie Zhang, Wu Wen, Fan Li, Yi Jian, Chuan-Ming Zhang, Meng-Xia Yuan, Ye Yang, Feng-Lin Chen
Abstract

BACKGROUND

Chicken skin mucosa (CSM) surrounding colon polyps is a common endoscopic finding with pale yellow-speckled mucosa during a colonoscopy screening. Although reports about CSM surrounding small colorectal cancer are scarce, and its clinical significance in intramucosal and submucosal cancers is unclear, previous studies have suggested it could be an endoscopic predictive marker for colonic neoplastic and advanced polyps. Currently, because of the inaccurate preoperative evaluation by endoscopists, many small colorectal cancers, particularly lesions with a diameter < 2 cm, are improperly treated. Therefore, more effective methods are required to better assess the depth of the lesion before treatment.

AIM

To explore potential markers of small colorectal cancer early invasion under white light endoscopy, providing patients with better treatment alternatives.

METHODS

This retrospective cross-sectional study included 198 consecutive patients [233 early colorectal cancers (ECCs)] who underwent endoscopy or surgical procedures at the Digestive Endoscopy Center of Chengdu Second People’s Hospital between January 2021 and August 2022. The participants had pathologically confirmed colorectal cancer with a lesion diameter < 2 cm and received endoscopic or surgical treatment, including endoscopic mucosal resection and submucosal dissection. Clinical pathology and endoscopy parameters, including tumor size, invasion depth, anatomical position, and morphology, were reviewed. Fisher’s exact test, the χ² test, and Student’s t-test were used to analyze the patient’s basic characteristics. Logistic regression analysis was used to examine the relationship between morphological characteristics, size, CSM prevalence, and ECC invasion depth under white light endoscopy. Statistical significance was set at $P < 0.05$. 

2 / 13
RESULTS

The submucosal carcinoma (SM stage) was larger than the mucosal carcinoma (M stage) with a significant difference (17.2 ± 4.1 vs 13.4 ± 4.6 mm, \( P < 0.01 \)). M- and SM-stage cancers were common in the left colon; however, no significant differences were found between them (151/196, 77% and 32/37, 86.5%, respectively, \( P = 0.199 \)). The endoscopic features of colorectal cancer revealed that CSM, depressed areas with clear boundaries, and erosion or ulcer bleeding were more common in the SM-stage cancer group than in the M-stage cancer group (59.5% vs 26.2%, 46% vs 8.7%, and 27.3% vs 4.1%, respectively, \( P < 0.05 \)). CSM prevalence in this study was 31.3% (73/233). The positive rates of CSM in flat, protruded, and sessile lesions were 18% (11/61), 30.6% (30/98), and 43.2% (32/74), respectively, with significant differences (\( P = 0.007 \)).

CONCLUSION

CSM-related small colorectal cancer was primarily located in the left colon and could be a predictive marker of submucosal invasion in the left colon.

**Key Words:** Chicken skin mucosa; Colonoscopy; Colorectal cancer; Submucosal invasion; White light endoscopy; Endoscopic features

**Core Tip:** Chicken skin mucosa (CSM) surrounding colorectal polyps is a relatively common clinical feature. Previous studies have found that it could be an endoscopic predictor of neoplastic and advanced colorectal polyps. However, it is unclear whether it is associated with early colorectal cancer or invasion. In our study, CSM-related small colorectal cancer was mainly found in the distal colon; this could be a potential predictive marker of submucosal invasion cancers located in the left colon. Since these cancers cannot be treated as a normal polyp, biopsy snare, cold-snare polypectomy, and cold-snare endoscopic mucosal resection may not be the appropriate options.
INTRODUCTION

Abnormal colorectal adenomatous mucosa is widely used as an indication to screen for colorectal cancer early. Chicken skin mucosa (CSM) is a mucosal anomaly defined by a pale-yellow speckled pattern in the colon and rectum observed under conventional white light endoscopy. It was first reported in 1998 and is characterized by fat accumulation in the lamina propria macrophages. Previous studies suggest that CSM is caused by colonic intestinal metaplasia, toxic factors from damaged intraluminal mucosa, or previous mild damage. Recent studies have observed that it may effectively predict colorectal adenoma and adenoma carcinoma[2,3]. However, its significance in intramucosal and submucosal cancers is unclear. Therefore, we retrospectively analyzed the endoscopic results of 233 patients with early colorectal cancer (ECC) (< 20 mm in diameter), including the tumor location, morphology, CSM features, and other conventional white light endoscopic findings, to improve endoscopists’ understanding of the white light endoscopic features of invasive colorectal cancer (< 20 mm diameter) to prevent misdiagnosis and reduce non-curative resection, thereby improving patient outcomes.

MATERIALS AND METHODS

Clinical data

CSM is a common endoscopic finding during a colonoscopy screening; it is a mucosal anomaly characterized by a pale-yellow speckled pattern surrounding the colon and rectum polyps observed before or after injection under conventional white light endoscopy. Patients aged between 18 and 85 years who underwent screening, surveillance, or diagnostic colonoscopy at the Digestive Endoscopy Center of Chengdu Second People’s Hospital between January 2021 and August 2022 were enrolled in this retrospective study. ECCs were screened based on the pathological results after
endoscopic or surgical operation. These are cancers with an invasion depth limited to the mucosa and submucosa, regardless of lymph node metastasis.

Our study complied with the diagnostic criteria of the Japanese Colorectal Cancer Research Association\(^\text{[4]}\). Intramucosal carcinoma refers to cellular or structural atypia to a certain extent, and the lesions are limited to the mucosal layer, confining the focus to the mucosal layer. Submucosal carcinoma (SM-stage cancer) refers to lesions where atypical cells break through the muscularis mucosae and infiltrate the submucosa.

The inclusion criteria were as follows: (1) Receiving endoscopic or surgical treatment, including endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD) or surgical treatment, and pathologically confirmed colorectal cancer; and (2) a lesion diameter < 2 cm.

The exclusion criteria were as follows: (1) A history of colorectal carcinoma (CRC) or inflammatory bowel disease; (2) familial adenomatous polyposis; (3) poor bowel preparation; and (4) a history of malignancy at other sites.

**Study equipment**

Standard colonoscopes were used throughout (CF H260AI, CF Q260AI, or CF Q290AI, Olympus Limited, Tokyo, Japan), and lesion size was measured *in vivo* using open biopsy forceps with a deployed diameter of 7 mm (QYQ-AXC2.3X2300, Changchun Huichun Medical Devices, China).

**Research method**

**Endoscopic findings:** The endoscopic imaging data of the patients were reviewed, and when the record was unclear or controversial, an experienced doctor reconfirmed. The lesion location and size, morphological classification under endoscopy, and morphological indexes for predicting ECC depth reported in previous literature were analyzed.

(1) Location: Tumors were either in the right (including the cecum, ascending colon, transverse colon, or splenic flexure) or left (including the descending colon, sigmoid
colon, and rectum) colon; and (2) Morphology: According to the Paris classification\[4], there were three types of tumors based on their endoscopic morphological characteristics, including protruded (0-I), flat (0-II), and depressed (0-III) types. According to whether the lesions had no pedicle, type 0-I polyp was classified into pedunculated and sessile lesions.

The following parameters\[5-7] facilitated ECC depth prediction: CSM, fold convergency, loss of lobulation, surface fullness, a depressed area with a clear boundary, a deeper red mucosal color, erosion or ulcer bleeding, and stalk swelling\[5-8]. The relationship between our results and ECC depth was determined using statistical analysis.

**Cure criterion:** Tumor invasion limited to the mucosal layer is referred to as mucosal carcinoma (M-stage cancer), and invasion into the submucosal layer without muscularis propria invasion is known as SM-stage cancer. With a boundary of the submucosal membrane (SM) of 1000 μm, the penetration depth to the inferior margin of the mucosal layer was defined as superficial submucosal membrane carcinoma (SM1), and that of > 1000 μm was defined as deep SM-stage cancer (SM2 and SM3).

All the cases in this study were adenocarcinomas, and the submucosal invasion depth was measured in SM-stage cancer specimens resected using ESD. The requirements for curative resection were as follows: (1) R0 resection; (2) an invasion depth of M- or SM-stage cancer of < 1 mm from the muscularis mucosa, or an invasion depth of pedunculated SM-stage cancer of < 3 mm from the Haggit’s level II; (3) no lymphatic or vascular vessel invasion; and (4) well- and moderately-differentiated adenocarcinoma. However, failure to meet any of the criteria above resulted in non-curative resection (Figure 1).

**Statistical analysis**

The statistical review of the study was performed by a biomedical statistician. Statistical analysis was performed using IBM SPSS Statistics, Version 23.0 (IBM Corp., Armonk,
NY, United States) based on the pathological diagnosis. Continuous variables are expressed as means ± SD. This study’s primary outcome was to evaluate the different endoscopic findings among small M- and SM-stage cancers. Patients’ baseline characteristics were analyzed using descriptive statistics. Furthermore, enumeration data are expressed as percentages or rates (%). Fisher’s exact test, the \( \chi^2 \) test, and Student’s \( t \)-test were used to analyze the patients’ basic characteristics, and the endoscopy revealed differences in CRC with different immersion depths. Statistical significance was considered at \( P < 0.05 \). Multivariate analysis was performed using logistic regressions. We included the data that had a level of significance at \( P < 0.05 \) or approximately 0.05 in the bivariate analysis as independent variables. This study’s statistical methods were reviewed by Yang Y and Chen FL from the Department of Chengdu Medical College Statistics.

RESULTS

Prevalence of ECCs and CSM

Between January 2021 and August 2022, 233 ECC cases (198 patients) were diagnosed under endoscopy and pathologically confirmed at our hospital. There were 133 males and 65 females, with a male-to-female ratio of 2.05:1. The patients’ ages were 29-85 years (median, 62.2 years). There were 196 and 37 cases of M- and SM-stage cancers, respectively, with a ratio of 5.3:1. M- and SM-stage cancers were commonly observed in the left colon. The diameter of M-stage cancer was \( 1.34 \pm 0.46 \) cm, and that of SM-stage cancer was significantly larger \( (1.72 \pm 0.41 \) cm). The diameters of all SM-stage cancers were \( >1 \) cm, and a statistical difference was observed between the groups (Table 1).

The CSM prevalence in this study was 31.3% \( (73/233) \). The positive rates of CSM in flat, pedunculated, and sessile lesions were 18% \( (11/61) \), 30.6% \( (30/98) \), and 43.2% \( (32/74) \), respectively, with significant differences \( (P = 0.007) \). The positive rate of CSM in sessile lesions was the highest. However, the positive CSM rate in the left colon was higher than that in the right colon \( (36.07\% \ vs \ 14\%) \), with a significant difference \( (P = \)
Lesions > 1 cm were more likely to reveal CSM (34.39% vs 18.18%), and the difference was significant ($P = 0.037$) (Table 2).

**Relationship between morphological characteristics and invasion depth under white light endoscopy**

Based on the endoscopic morphological classification, elevated lesions (73.8%, 172/233) were more common than flat lesions (26.2%, 61/233). In this study, the proportions of flat and sessile lesions were higher than that of M-stage cancer; however, no significant difference was observed between the types at different depths of invasion. The number of laterally spreading tumors (LSTs) included in 0-IIA lesions and SM-stage cancer was low and could not be further stratified. In addition, the 0-IS + 0-IIC type was classified as 0-IS type, 0-IIA + 0-IIC type as 0-IIA type, and 0-IIC + 0-IIA type as Iic type (Table 3).

CSM is a depressed area with clear boundaries, erosion, or ulcer bleeding, and these features are more common in SM-stage cancers. In total, 59.5% (22/37) of cases had “chicken skin” changes in the basal mucosa around the SM-stage cancer lesion; however, the corresponding number in M-stage cancer was 26.2% (51/196), and the difference was significant ($P < 0.001$). In 45.9% (17/37) of SM-stage cancers, local depressions with clear boundaries were observed, whereas these were observed in 8.7% (17/196) of M-stage cancers, and the difference was significant ($P < 0.001$).

The proportion of local erosion or ulcer bleeding in M-stage cancer was 4.1% (8/196), whereas it was 27.3% (10/37) in SM-stage cancer, and the difference was significant ($P < 0.01$). There were 98 0-Ip and 0-Isp lesions, including 87 M- and 11 SM-stage tumors. Stalk swelling was observed in 13.8% (12/87) and 54.6% (6/11) of M- and SM-stage tumor cases, respectively. The $P$-value of Fisher’s exact probability analysis was 0.04. However, its significance should be further explored using data from a larger sample. Therefore, if “chicken skin” changes and local depressions with clear boundaries, local erosion, or ulcer bleeding are observed under white light endoscopy, possible lesion invasion of the submucosa should be considered. However, no significant difference was observed in the proportion of mucosal fold convergency, loss of lobulation, surface
fullness, and deeper red mucosal color between M- and SM-stage cancers \((P > 0.05)\) (Table 4). Logistic regression results showed that CSM, a depressed area with clear boundaries, erosion, or ulcer bleeding, and size \((\geq 10\ \text{mm})\) were independent risk factors for submucosal invasion in ECC (Table 5).

**Relationship between CSM prevalence and invasion depth of ECC**

Further stratification based on the growth morphology of the lesions revealed that the positive rates of CSM in flat-type SM- and M-stage cancers were 41.64\% \((5/12)\) and 12.24\% \((6/49)\), respectively, with a significant difference \((P = 0.03)\).

The positive rates of CSM in protruded-type SM- and M-stage cancers were 63.64\% \((7/11)\) and 26.44\% \((23/87)\), respectively, with a significant difference \((P = 0.03)\). Furthermore, the positive rates of CSM in sessile-type SM- and M-stage cancers were 71.43\% \((10/14)\) and 36.67\% \((23/87)\), respectively, with a statistical difference \((P = 0.02)\) (Table 6). According to the results of logistic regressions, submucosal invasion, anatomical position (left colon), and growth morphology (pedunculated or sessile) were independent risk factors for CSM changes in ECCs (Table 7).

**DISCUSSION**

According to statistics, the incidence and mortality rates of CRC rank third and second in the incidence and death spectrums, respectively, of malignant tumors\(^9\). The CRC incidence and mortality rates also have an increasing trend in China. However, early diagnosis and intervention can considerably improve the quality of life and the 5-year survival rate of patients with CRC. Endoscopic treatment is feasible for colorectal precancerous lesions, M-stage cancer, and colorectal cancer confined to SM1. However, surgical treatment is necessary for patients with an invasion depth exceeding a third of the upper submucosa due to the high lymph node metastasis rate\(^10\). Therefore, an accurate judgment of tumor nature, size, and depth of invasion under endoscopy is a vital prerequisite for making tumor treatment choices. Combining narrowband imaging and magnifying endoscopy has been consistently recognized for identifying and
diagnosing early tumors, with improved detection rates of early and advanced cancers\textsuperscript{[11]}. However, many primary hospitals lack the conditions for routinely using magnifying endoscopy and can only screen using conventional white light endoscopy. Furthermore, the current understanding of such lesions is insufficient, particularly those with a diameter < 2 cm. Before the pathological tissue evaluation, it is challenging to judge the nature and invasion depth of lesions under conventional white light endoscopy, which may lead endoscopists to select inappropriate treatment; however, it cannot achieve curative resection. The definition of colorectal cancer differs between Western countries and Japan, and this study referred to the Japanese Society for Colon Cancer Research and Vienna classification criteria\textsuperscript{[4,12]}. M-stage cancer refers to a certain degree of cellular or structural atypia where the lesion is confined to the mucosal layer. In contrast, SM-stage cancer refers to lesions where abnormal cells break through the muscularis mucosa and infiltrate the submucosa. In SM-stage carcinoma, if the immersion depth exceeds 1000 \( \mu \)m of the submucosal layer, there is a metastasis risk of 6\%-12\%\textsuperscript{[13]}. At this time, endoscopic resection cannot attain curative standards; therefore, it is unsuitable for treatment, and clinicians should pay more attention. Endoscopists frequently select treatment based on the location, shape, and endoscopic appearance of the lesion\textsuperscript{[14]}. In this study, the most common sites of ECCs were the rectum and sigmoid colon, consistent with the common site of colorectal cancer in the left colon. Moreover, the lesion diameter affects the depth of ECCs invasion. The diameter of SM-stage cancers was significantly larger than that of M-stage cancers, and there was a significant difference between the groups. Furthermore, the SM-stage cancer diameter was > 1 cm, similar to the conclusion of a previous study\textsuperscript{[5]}. According to the literature, the lesion morphology of ECC detected in Western countries is mainly the hump type (0-I type). Conversely, this study’s results were similar to the protruded type (0-I type). The proportion of protruded type (0-I type) lesions was 73.82\%, possibly because hump-type lesions are easier to detect than flat types during colonoscopy. In this study, the proportions of flat, pedunculated, and sessile lesions in ECCs with different depths of invasion were similar, without significant differences. Because of the
few 0-IIa, 0-IIa + 0-IIc, 0-IIc + 0-IIa, and LST lesions, further detailed stratification and comparison were not performed.

According to the literature, CSM, fold convergency, loss of lobulation, surface fullness, a depressed area with a clear boundary, deeper red mucosal color, erosion, or ulcer bleeding, and stalk swelling under standard white light endoscopy are commonly used to analyze the depth of invasion of ECC. In this study, the sessile lesions, left hemicolons, and lesions > 1 cm had a higher positive rate of CSM, which is consistent with the results of previous studies[1-3].

CSM is an endoscopic finding with uniform yellow-white spots around the lesion base, and the corresponding pathological manifestation is fat accumulation in the lamina propria macrophages. It is similar to the endoscopic appearance of gastric xanthoma. CSM is not the same as white spots, which are associated with invasive cancer, and is effective in inhibiting the progression of lesions with high malignant potential[15]. The CSM was classified into two based on their characteristics in related research[3]. Type 1 CSM was obvious under a white light endoscope and could be confirmed before injection, which was similar to white spots. However, type 2 differed from white spots and was certainly difficult to detect under the routine white light endoscopy screening. Therefore, the submucosal injection (NS: Normal saline + methylene blue) was needed, and CSM was observed in the bulging mucosa and the blue background of the mucosa.

The histopathology revealed foam cells filled with lipids in the mucosa. Furthermore, it is regarded as a compensatory response to polyp growth[16]. However, a study in 2012 reported that the expression levels of proliferation markers (ki-67, COX-2) were higher in adenocarcinomas and adenomas with CSM[17]. A recent study revealed that CSM is associated with carcinogenesis and its progression[18]. Macrophages are important immune cells vital to cancer pathophysiology progression. The stool is retained in the left colon for a longer time; therefore, because of the retaining stool, bacteria, and macrophages, more bowel inflammation is experienced. Therefore, the abnormal
inflammation or increased expression of inflammatory genes may have resulted in tumorigenesis despite the lack of macrophages revealing CSM.

Currently, for the endoscopic resection of lesions without signs of submucosal invasion, cold snare polypectomy is recommended for lesions smaller than 10 mm; EMR is recommended for non-pedunculated lesions larger than 20 mm according to the European Society of Gastrointestinal Endoscopy clinical guidelines and the United States Multi-Society Task Force[19,20]. However, the optimal resection method of 10-20 mm (medium size) remains controversial, and whether hot or cold resection is preferable remains unclear. Recently, some studies have demonstrated that cold-snare EMR can be safely performed en bloc for 10-14 mm colorectal adenomas without severe adverse events. However, the histological complete resection rate and submucosal layer found in the resected specimens were 63.8% and 25.0%, respectively[23]. For early-stage small colorectal cancer with submucosal invasion, this resection is non-curative. Therefore, it is crucial to determine whether the ECC has a submucosal invasion before the surgical choice of treatment and the prognosis of patients. Our study can be useful in this regard.

Previous studies have revealed that surface fullness is an important characteristic of ECC; however, this study’s results reveal that it is not vital to determine whether the tumor invades the submucosa. The primary reason could be that the surface fullness mainly reflects tumor growth expansion. When it progresses to a certain stage, with tumor volume increase, particularly deep infiltration, the surface tumor cells may have different extents of necrosis, resulting in different degrees of well-defined surface depressions. Fold convergency and loss of lobulation showed no differences in ECCs with different depths of invasion, whereas the P-value of the difference in the stalk swelling in ECCs with different depths of invasion was approximately 0.05, which may be due to the small sample size of this study, which requires further discussion.

This study had some limitations. First, we did not further measure the specific submucosal infiltration depth, distinguishing SM1, SM2, and SM3 for surgical resection and EMR resection of patients with submucosal infiltration. Therefore, this may have
impacted the preoperative evaluation and treatment selection. Second, we did not define surveillance colonoscopy after EMR and ESD. The current European and United States guidelines recommended a 3-year surveillance colonoscopy for patients with adenoma larger than 10 mm; hence, the true complete resection rate and the necessity of additional treatment in this study require our regular review and further evaluation following the recommendations in the guidelines. Third, this study was a single-center, retrospective clinical analysis. In addition, the sample size was limited, and the study’s single-center nature may have caused bias. Therefore, using a larger sample size and multi-center clinical study is necessary to elucidate the relationship between endoscopic appearance and immersion depth from the perspective of fine cell segmentation.

CONCLUSION

CSM has a clinicopathological value for predicting deep immersion in early CRC in the left colon. It can enable endoscopists to better identify the submucosal infiltrates of ECC, thereby providing patients with more appropriate treatment options.
