Amebic liver abscess: Clinico-radiological findings and interventional management

Rajeev Nayan Priyadarshi, Ramesh Kumar, Utpal Anand

Abstract
In its classic form, amebic liver abscess (ALA) is a mild disease, which responds dramatically to antibiotics and rarely requires drainage. However, the two other forms of the disease, i.e., acute aggressive and chronic indolent usually require drainage. These forms of ALA are frequently reported in endemic areas. The acute aggressive disease is particularly associated with serious complications, such as ruptures, secondary infections, and biliary communications. Laboratory parameters are deranged, with signs of organ failure often present. This form of disease is also associated with a high mortality rate, and early drainage is often required to control the disease severity. In the chronic form, the disease is characterized by low-grade symptoms, mainly pain in the right upper quadrant. Ultrasound and CT play an important role not only in the diagnosis but also in the assessment of the disease severity and identification of the associated complications. Recently, it has been shown that CT imaging morphology can be classified into three patterns, which seem to correlate with the clinical subtypes. Each pattern depicts its own set of distinctive imaging features. In this review, we briefly outline the clinical and imaging features of the three distinct forms of the ALA, as well as discuss the role of percutaneous drainage in the management of ALA.
INTRODUCTION

Amebic liver abscess (ALA) is an infection caused by protozoan *Entamoeba histolytica* (EH), an intestinal parasite. The infection is acquired by ingestion of water or food contaminated by EH cysts (the infective stage of the parasite). The cysts resist gastric juice and reach the distal ileum, where they undergo excystation producing trophozoites (the feeding stage of the parasite). In > 90% patients, the trophozoites feed over intestinal tissue and bacteria without producing symptoms. In less than 1% of the cases, however, the trophozoites penetrate the mucosa and, through the portal route, reach the liver causing liver abscess [1]. ALA is the most common and has the highest mortality of amebiasis manifestations. It continues to remain the most common cause of liver abscess in developing and underdeveloped countries [2-6].

ALA was known as a progressive and deadly disease a century ago; however, since the introduction of modern antibiotics, the mortality has drastically reduced to 1 to 3% [7]. Metronidazole is the most effective agent, with cure rates of approximately 90%. Most patients become asymptomatic within 72 to 96 h of treatment, and drainage adds no benefit to uncomplicated cases [7,8]. This fact seems to be more relevant for a typical case where the patient presents the classic and the most common form of the disease, i.e., subacute mild disease. Reports from endemic areas have shown that a greater percentage of cases require drainage through either needle or catheter. The reported prevalence of such cases varies from 44 to 80% [3-5,7,9-14]. A thorough literature search shows that two distinct clinical settings usually require drainage. In the first, the patients present acutely with the severe and fulminating disease, and drainage is performed to control the disease progression and prevent organ failure. Such abscesses, by different authors, have been denoted by different terms that indicate the aggressive nature of the disease, such as “acute aggressive ALA”, “severe ALA” or “fulminant ALA” [10,15-17]. In the second clinical setting of the disease, the patients present late with mild symptoms, usually tenderness; they usually have a large persistent abscess despite medical therapy. Various terms are used to describe such abscesses, such as “drug-resistant ALA”, “refractory ALA” or “chronic indolent ALA” [18-22]. Regardless of the
presentations, most cases are usually associated with a few complications, such as rupture, secondary infection or biliary communication. Considering this fact, a few authors prefer referring to it as “complicated ALA” [15,14]. Therefore, ALA can be classified into three clinical subtypes: subacute mild, acute aggressive and chronic indolent. Not only do the ALAs have varied clinical presentations, but they are also associated with distinct imaging patterns [10]. This review describes the three major types of clinical presentations as well as three types of imaging patterns (correlating with clinical subtypes). Special emphasis has been placed on the two clinical types — acute aggressive and chronic indolent. This paper also discusses the complications of ALA and their percutaneous management.

OVERVIEW OF EPIDEMIOLOGY, RISK FACTORS AND PATHOGENESIS OF COMPLICATED ALA

Epidemiology

Although ALA occurs globally, most reports emerge from endemic countries, such as India, Sri Lanka, Bangladesh, Mexico, East and South Africa or parts of Central and South America [23]. A high endemicity in these countries is related to poor hygiene and sanitation since the parasite is transmitted via the fecal-oral route. Even in endemic countries, ALA occurs primarily in rural areas where defecation in the open air is a common practice [11,24-26]. The lack of adequate sewage disposal results in contamination of drinking water with the EH cysts. Using polymerase chain reaction (PCR), a population-based study from India has detected the prevalence of EH in 14% of the stool samples [27]. In developed countries, ALA occurs mostly in travelers or immigrants from endemic areas [28]. Apart from endemicity, several other epidemiological factors also increase the risk of developing complicated disease.

Risk factors

The disease is found almost exclusively in men (male: female > 10:1) [11]. The reason for this is unknown but several investigators have speculated that it might be related to alcohol, particularly those prepared locally from sap of palm trees (toddy) [11,24,25,29]. Not
only is the toddy a risk factor for ALA, but in many studies it has been linked to severe disease\textsuperscript{[13,30]}. The exact mechanism by which it contributes to pathogenesis of ALA is unclear. It has been proposed that alcohol may alter the gut mucosa or convert the pathogen to more virulent strain or render the liver more susceptible to the infection\textsuperscript{[23,24,29]}. Most cases occur in middle age ranging from 20 to 50 years\textsuperscript{[30]}. In older patients, the disease tends to be more severe possibly due to their poor immunity, whereas it is found to be rare in children\textsuperscript{[31]}. Another factor contributing to the pathogenesis of ALA is malnutrition\textsuperscript{[11,15,23]}. For centuries, the disease has been a symbol of poverty. A typical patient of ALA, as we have observed, is a thin emaciated villager belonging to a low socioeconomic status. Their poor nutritional status is evidenced by low albumin, BMI and hemoglobin\textsuperscript{[11]}. ALA has also been shown to be severe in diabetic patients\textsuperscript{[16,32]}.

\textit{Pathogenesis}

The term “amebic liver abscess” is a misnomer as the cavity formation or liquefaction is not due to suppuration; rather, it is the result of a unique type of necrosis\textsuperscript{[33,34]}. The necrotic area appears as if it has been dissolved by chemical or toxin. Considering this morphological pattern, it was believed that the parasite possesses a toxin that lyzes the hepatocytes, and therefore the parasite was named “\textit{histolytica}”\textsuperscript{[35]}. \textit{It is now known that several proteolytic enzymes released by the inflammatory cells are responsible for the tissue destruction}\textsuperscript{[7,36,37]}.

Understanding of the gross morphology is important because it is characteristic and, to a large extent, can be extrapolated to imaging findings\textsuperscript{[35,38,39]}. The gross appearance varies depending on the severity and the duration of the disease. In the early stage, it is that of a necrotic area where the center has liquefied necrotic tissue (chocolate-colored sterile “pus”); however, the periphery has more solid tissue\textsuperscript{[10,35,38-40]}. The peripheral solid and partially liquified tissue is responsible for the shaggy or ragged appearance on the wall\textsuperscript{[10,40]}. A mature wall is absent and the tissue surrounding the abscess is congested, compressed and edematous\textsuperscript{[43]}. There may be pressure over the surrounding liver parenchyma or the hepatic capsule. Venous thrombosis and ischemic infarction are
commonly observed in fatal cases\textsuperscript{[42]}. As the abscess heals, a fibrous wall forms and the cavity becomes more sharply defined\textsuperscript{[38,43]}. The edema and congestion regress and the abscess wall is surrounded only by a thin rim of edema. The peripheral solid tissue becomes more liquefied, the content is gradually resorbed, and the lesion heals completely without scar. However, a complicated or a very large abscess can persist in the form of a residual abscess with a thick fibrous wall. A mature wall, as opposed to the ragged wall, indicates chronicity or secondary infection\textsuperscript{[42]}.

ALA is usually solitary, located in the right lobe of the liver. The size varies from a few centimeters to 20 cm\textsuperscript{[35]}. However, the risk of complications increases with the number and size. In autopsy series, unlike successfully treated series, 60\% of cases show multiple abscesses with their size varying from 10 to 15 cm\textsuperscript{[35]}. Literature shows a higher incidence of large (\geq 5 to 10 cm) and multiple abscesses (occurring in about 50\% of cases) among Southeast Asian population compared to other studied populations\textsuperscript{[8-11,43-47]}.

**CLINICAL PRESENTATION**

The clinical presentation varies from mild to severe. Based on the duration and the severity, ALA can be classified into three main types: subacute mild, acute aggressive, and chronic indolent\textsuperscript{[10,15,23,28,48]}

*Subacute mild ALA*

Most patients (approximately 80\%) have a subacute course characterized by mild symptoms that develop in less than 2 to 4 wk\textsuperscript{[25,28,30,49,51]}. The disease typically begins with fever and chills, right upper quadrant pain and tender hepatomegaly. Other symptoms include anorexia, weakness, nausea and diarrhea. There may be right shoulder pain when an abscess located in the posterolateral segments irritates the diaphragm. The typical finding on physical examination is point tenderness in the intercostal spaces\textsuperscript{[31]}. The disease is associated with no or minimal organ dysfunction; the laboratory parameters are near normal except mild to moderate leukocytosis. Dramatic improvement is observed after medical therapy and no further complications
occur. This pattern of presentation has also been referred to as “acute benign ALA” by a few authors; however, the term “subacute mild” may be preferable because it correctly defines the clinical course of the disease [15,48]. Additionally, the term also differentiates it from the two other forms of the disease, i.e., acute aggressive ALA and chronic indolent ALA.

**Acute aggressive ALA**

Acute aggressive ALA is characterized by a more severe and rapidly progressive course. Considering the acuteness and severity of this form, Katzenstein *et al* named it as “acute aggressive ALA” [15]. The prevalence of this type of ALA may be high in endemic areas [10]. In a study of 317 patients with ALA, Balasgaram reported acute fulminating infection in 13% of cases [17]. The patients often present more acutely (< 10 days) with signs of severe disease including systemic toxicity, high fevers and chills, and an exquisitely tender hepatomegaly [15]. Signs related to rupture and other complications may be present. In fact, rupture is a common presenting manifestation of aggressive ALA, occurring in up to 57% of patients [10]. The patients with free intraperitoneal rupture often have features of generalized peritonitis. Sepsis-like features can occur in more severely affected patients. Up to 90% of patients require hospitalization and about 13% require ICU care [10]. Signs of organ dysfunction, such as jaundice, may also be observed in most patients [9,12,32]. Renal dysfunction can occur in 5 to 12% of cases [6,10]. Hepatic failure and encephalopathy may also occur. Approximately, one-third to one-half of the patients will have gross fluid derangements including ascites, pleural effusion and edema [5,9,10,13,52]. Patients with aggressive ALA are often misdiagnosed as having acute cholecystitis, appendicitis or bowel perforation [30,53-55].

Most patients with aggressive ALA will have markedly deranged laboratory parameters, such as severe leukocytosis, hyperbilirubinemia, hypoalbuminemia, elevated liver enzymes, and elevated alkaline phosphatase [10]. A high mortality has been recorded in this group of patients. Most deaths are usually related to intraperitoneal rupture, which is followed by sepsis and multiorgan failure. Many
findings of aggressive disease have been identified as poor prognostic markers in different studies, such as multiple abscesses, large (>500cc) volume abscesses, presence of encephalopathy, hypoalbuminemia, hyperbilirubinemia (>3.5 mg/dL)\(^\text{[3,9,13,32]}\). Medical therapy alone is often suboptimal to control the disease and the laboratory tests do not return to near normal following treatment. Therefore, drainage with either needle or catheter is usually required \(^\text{[10,15]}\).

**Chronic indolent ALA**

Chronic presentation can occur in approximately 10 to 20% of cases \(^\text{[10,15, 23,49,56,57]}\). This presentation has been designated in most studies as “chronic indolent ALA”. In this form, patients present late with mild symptoms for more than four weeks. Most patients complain of pain over the right lower chest or upper abdomen. Fever is usually absent or of low grade. However, a history of fever with chills at the onset of the disease may be obtained in most cases. Additionally, many patients will have a history of prior medical treatment or sometimes prior needle aspirations. On examination, right upper quadrant tenderness is usually present. Other low-grade symptoms include weight loss, anorexia, or malaise \(^\text{[10,15]}\). Laboratory tests are usually normal except elevated alkaline phosphatase level and low serum albumin. Leukocytosis in chronic abscesses suggests the presence of secondary infection, which is the most common complication in this form of the disease. In contrast to acute aggressive ALA, chronic ALA is rarely associated with intraperitoneal rupture.

**LABORATORY EVALUATION**

The diagnosis of ALA is based on recognition of the typical clinical features, imaging studies and serological tests. Serological tests are considered confirmatory (sensitivity > 94%; specificity > 95%) \(^\text{[7]}\). However, their usefulness in the diagnosis of acute ALA is limited in endemic areas because the tests remain positive for several months to years after resolution of infection. Moreover, the serological tests may be negative in the first seven to ten days of the infection, limiting its diagnostic use for acute ALA \(^\text{[7]}\).
Routine laboratory tests in ALA are nonspecific and do not differ from those in pyogenic abscess\textsuperscript{[58,59]}. However, these tests are useful in assessing the severity and monitoring the treatment response. In most patients with acute benign ALA, mild to moderate leukocytosis is found with an average WBC count of 16,000/\(\mu\)L. However, a high WBC count above 20,000/\(\mu\)L should suggest either aggressive, or secondarily infected abscesses\textsuperscript{[9,56,60]}. In our series, a mean of 24,000/\(\mu\)L was found in patients with aggressive abscesses. Serum bilirubin and liver enzyme (AST/ALT) levels are normal or minimally elevated in mild cases. When elevated, the AST/ALT levels return to normal following medical therapy. However, the alkaline phosphatase level is elevated in 70 to 80 \% of cases, regardless of the severity of the disease and the duration of presentation\textsuperscript{[56,60]}. A very high value of bilirubin (> 3.5 mg/dL) and liver enzymes indicates complications or aggressive disease. A low serum albumin (< 2 g/dL) is found in almost all patients; however, an exceedingly low value is a poor prognostic marker\textsuperscript{[34]}. Inflammatory biomarkers, such as C-reactive protein and procalcitonin have been found to be nonspecifically raised in most patients with ALA\textsuperscript{[34,59,61]}.

\textbf{IMAGING EVALUATION: IMAGING CLASSIFICATION AND CLINICORADIOLOGICAL CORRELATION}

Chest radiographs, ultrasound, CT, and MRI are the most employed modalities for diagnosis of ALA. Radiographs are insensitive, non-specific and are abnormal only in half of the cases\textsuperscript{[23]}. They can reveal elevated diaphragm, pleural effusion and basal consolidation or atelectasis. MRI seems to offer no advantage over CT\textsuperscript{[33,62]}. Of all radiological tests, ultrasound and CT are the most employed tools; in fact, they are complementary to one another in many ways. For example, ultrasound can detect the degree of liquefaction, differentiating solid necrotic tissue from more liquefied tissue; this information is not provided by CT. Ultrasound, however, can fail to detect an early abscess when the lesion is not liquid enough to be promptly visible\textsuperscript{[63]}. CT is more sensitive in this regard. Another concern with ultrasound may be that early aggressive abscesses might be mistaken for necrotic malignant mass because they often contain
solid (non-liquefied) necrotic material \[8,38,39,47\]. Because of its ability to differentiate viable tissue from necrotic tissue, contrast-enhanced CT can distinguish between necrotic mass and aggressive abscesses. Additionally, CT is useful in identification of various complications associated with ALA. Although both ultrasound and CT are highly sensitive (ultrasound, 85-95%; CT, 100%) \[64\], their specificity is low for differentiating ALA from other infective abscesses or necrotic masses \[45\].

The imaging features of ALA on CT have been described as round oval hypodense lesions with a rim enhancing wall and on sonography as hypoechoic or anechoic lesions with internal echoes. This classic description of ALA, however, does not take into account the entire spectrum of the imaging findings, which are known to vary considerably. The varied morphology has largely been shown to reflect the underlying pathological changes, which occur as ALA evolves through the different phases of maturation. Acute abscesses consist mainly of solid necrotic tissue and their edges are irregular or ragged. As the abscesses heal, there is formation of a distinct wall, edges become smooth, and the contents become more liquefied \[10,38,43\]. This morphologic variation has prompted several investigators to classify the imaging features of ALA into distinct types \[46,65,66\]. Most investigators have classified ALA into three types based on sonographic appearance. In 1987, Leonetti et al. divided the sonographic morphology into three stages: pre-suppurative stage (phase I), suppurative stage (phase II), and scarring stage (phase III) \[65\]. Subsequently, N'Gbeso et al. proposed a similar sonographic classification: non-collected ALA (type I), collected ALA (type II), and healed ALA (type III) \[66\].

On MRI, variable degree of wall formation and edema surrounding ALA have been reported according to the status of abscess healing. Elizondo et al., who examined 29 ALAs with MRI, have reported that untreated ALAs are associated with incomplete ring (corresponding to incomplete wall) and diffuse or wedge-shaped perilesional edema \[43\]. Following successful treatment, the ring formation is complete and the edema regresses to form concentric rings around the abscess. Matching with the MRI
findings, double-target sign has been described on contrast-enhanced CT; the inner ring corresponds to the enhancing wall and the outer ring to the perilesional edema. Our recent experience suggests that the latest generation CT can effectively evaluate several imaging characteristics, such as wall formation, degree of liquefaction, enhancement patterns, septa, or perilesional hypodensity. These characteristics can provide considerable information about the patient’s clinical status. It appears that imaging findings of ALA can be classified into three distinct but overlapping patterns (type I, II and III) that correlates well with the clinical subtypes (Table 1). This classification may be useful for identifying those abscesses that would require more aggressive treatment.

**Type I: ALA with ragged edge**

Type I pattern is observed in patients with acute aggressive ALA. It is characterized by incomplete or absent walls and ragged edges (Figure 1). This pattern is observed in patients with acute aggressive ALA. Type I pattern indicates an early and progressive abscess, with no sign of healing. Surrounding the abscess, there is a diffuse or wedge-shaped hypodensity, which is usually due to the combined effect of hypoperfusion and edema. Most cases show irregular and interrupted enhancement at the edges. Multiple irregular septa may be observed at the periphery, indicating the viable parenchyma that is yet to be necrotic. On sonography, they appear heterogeneous due to the presence of both solid and liquefied necrotic tissue. The heterogeneity accounts for the frequent misdiagnosis of aggressive ALA as malignant lesions. Other imaging features often associated with type I morphology are large size, multiplicity, and irregular shape (due to coalescence of multiple lesions).

**Type II: ALA with complete rim enhancing wall**

Type II pattern indicates subacute mild ALA. It is characterized by a well-defined enhancing wall (Figure 2). The rim enhancement of the wall indicates active granulation tissue, a pathological sign of inflammation and beginning of healing. A thin rim of edema surrounding the wall (in contrast to the more widespread edema of type I pattern) may be observed to form a perilesional “halo” on contrast CT. In many cases, a
double-target sign (the inner ring of wall enhancement and outer ring of hypodense edema) is identified. The content is more liquefied and homogeneous compared to those presenting acutely. This pattern is nonspecific and resembles pyogenic abscesses [43,69,70].

**Type III abscess: ALA with non-enhancing wall** [10]

Type III pattern represents chronic indolent ALA. It is characterized by a thick fibrotic wall that is much smoother and does not enhance with contrast (Figure 3). The absence of contrast enhancement excludes active inflammation. This pattern, in fact, represents persistence of amebic pus (usually more than four weeks), in which the liver fails to clear the necrotic tissue. The abscesses in this form are usually asymptomatic; however, when they are large enough to cause capsular stretching, they can cause right upper quadrant pain. Clinicians should be aware that healed ALAs in this pattern often resemble cyst and can persist for months or years following successful treatment [46,66,71,72].

**COMPLICATIONS: CLINICO-RADIOLOGICAL FINDINGS**

**Rupture:**

The most feared complication of ALA is rupture. The overall incidence ranges from 6 to 40% [10,44,52,73]. ALA generally ruptures into the thoracic cavity or intraperitoneal space. Occasionally, the abscess can rupture into hollow viscera, such as the stomach, duodenum, or colon [20,60,74,75]. Of all ruptures, the gravest, but fortunately rare, is the rupture into pericardium [46]. In our experience, the risk of free intraperitoneal ruptures is high when the abscesses present acutely (type I pattern). However, intrathoracic ruptures, particularly the intrapulmonary ones, are noted more frequently in chronic cases (type II or III pattern). This may be due to development of adhesion between diaphragm and pleura in older abscesses [10].

**Intrathoracic Rupture: Pleural Empyema, Lung Abscess, Hepatobronchial Fistula**

Pleuropulmonary rupture occurs in 7 to 20% of patients [7,56,57]. The abscesses located inferior to the diaphragm can perforate it to enter pleural space causing amebic
empyema, which is the most common intrathoracic complication. It is important that pleural empyema be differentiated from sterile pleural effusion, which occurs more frequently than empyema. The sterile effusion is reactionary and resolves spontaneously, and therefore, it requires no drainage \[57\]. The presence of loculations and septations on ultrasound indicate amebic empyema \[11\]. The next intrathoracic complication is the development of lung consolidation or lung abscess, which occurs when an abscess directly ruptures into lung parenchyma invading through both diaphragm and pleura. The lung abscess may, in turn, communicate with the bronchi to cause hepatobronchial fistula or with pleura to cause bronchopleural fistula. Bronchial communication has been reported to occur in over one-third of thoracic complications \[76\]. The presence of air in the lung abscess or liver abscess or in the pleural collections indicates these fistulous complications (Figure 4) \[11\]. Clinically, the patients complain of productive cough, often expectoration of amebic pus like material. The pleuropulmonary rupture is considered less severe than the intraperitoneal rupture because of spontaneous drainage of the abscesses following the hepatobronchial fistula.

**Intraperitoneal Rupture: Contained Rupture Versus Free Rupture**

Intraperitoneal rupture has been said to occur in only 7% of the cases \[7,56,57\]. However, we have found 33% incidence of intraperitoneal rupture in our series \[10\]. In fact, several series from endemic countries have reported similar findings \[6,13,17\]. Based on imaging findings, the intraperitoneal ruptures can be divided into two types: contained rupture and free rupture \[11,60\]. The contained rupture is characterized by accumulation of the localized fluid collection around the liver, usually in the subphrenic or subhepatic space (Figure 5) \[11\]. The localized fluid from the contained rupture may occasionally be palpable on abdominal examination. This type of rupture carries a good prognosis and fortunately, is more common than its counterpart — the free rupture. The free rupture is characterized by the fluid collection that diffusely involves the entire peritoneal cavity; they can cause generalized peritonitis and carry a poor prognosis (Figure 6). The
differentiation between these two types is significant as more aggressive treatment for longer duration is required for free ruptures\(^{[11,21]}\).

**Biliary Complication: Communication Versus Compression**

A common cause of drug failure is the presence of biliary complications, which has been reported to occur in up to 27\% of refractory cases\(^{[12,22,77]}\). This occurs either from ductal communication with the abscess or from external compression by a large abscess\(^{[12,41]}\). When the liver parenchyma is destroyed by an aggressive abscess, the bile ducts are also damaged, producing ductal communications\(^{[12]}\). Usually, the communication is subtle, and therefore, ductal dilatation may not be evident on imaging. In several cases, the diagnosis is made only during percutaneous drainage when the initial aspirated fluid is bilious or when bile (usually persistent) appears thereafter\(^{[11,22,77]}\). Uncommonly, an abscess, particularly when large and aggressive, can rupture into the central bile ducts, causing duct dilatation (Figure 7). In such cases, the diagnosis may be confirmed when endoscopic retrograde cholangiopancreatography (ERCP) or cavitogram demonstrates contrast extravasation into the abscess cavity\(^{[22,55]}\). Usually, the bile ducts are compressed by a large abscess, resulting in biliary duct dilation; these cases are evident on ultrasound or CT. The size and location of an abscess on imaging can provide anatomic clues to the presence of a biliary complication. The large (> 5 to 10 cm) and centrally located abscesses (near porta hepatitis) are more likely to have biliary complications than those smaller and have subcapsular locations\(^{[12]}\). Clinically, the presence of high jaundice may indicate biliary complications. Agarwal et al compared the abscesses with and without biliary communications and found that total bilirubin levels >2 mg/dL were present only in the patients with biliary complications\(^{[22]}\).

**Secondary Bacterial Infection**

ALA is typically sterile. However, in 10 to 20\% of the cases, it can be complicated by secondary bacterial infections\(^{[58,78,79]}\). The incidence may be higher than generally recognized. Recently, in a PCR based study from liver aspirates, Singh et al found bacterial infection in 37\% of cases, mostly anaerobes of intestinal microbiota\(^{[2]}\).
authors suggested that intestinal bacteria reach the liver along with the trophozoites through the portal route, that is, concurrent or coinfection with bacteria. When secondary bacterial infection occurs as coinfection, the disease may take an aggressive course. This complication should be suspected in refractory cases, particularly those associated with persistent high fever and marked leukocytosis (> 20,000/µL) [56]. Another mechanism of secondary infection is bacterial superinfection, which usually occurs in the stagnant fluid following unsuccessful needle aspiration or inadequate catheter drainage [18]. Since most of the abscesses are walled off at this point, symptoms are of chronic indolent disease. In contrast to sterile amebic aspirate, cultures of pus from secondarily infected ALA usually yield positive results. Blood cultures, however, may be negative because most patients are generally pretreated with antibiotics [80].

Vascular complication: venous thrombosis, venous compression and arterial aneurysm

Venous thrombosis is a common phenomenon in this disease. Autopsy studies have shown that venous thrombosis occurs in up to 30% of cases; however, we have identified venous thrombus in 70% of cases with the use of the latest multidetector CT [42,68]. Venous thrombosis may involve the portal or hepatic vein, but usually both are involved. Thrombus typically occurs in the smaller segmental or subsegmental branches. The hepatic vein thrombosis can extend into IVC or even into the right atrium [68]. Rarely, it can cause a Budd-Chiari like syndrome [81]. Detection of thrombus in large veins may be indicative of severe ALA [68,82]. The diagnosis of thrombosis on CT can be suggested by the presence of a wedge-shaped hypoattenuating area surrounding the abscess, which might be due to thrombosis led hypoperfusion [83]. Another vascular complication is compression of the intrahepatic veins and the IVC. Venous compression may be a clue to the presence of a high intracavitary pressure in the abscess, which in turn indicates aggressive abscesses. IVC compression occurs when a large abscess located in the caudate lobe compresses the IVC, causing leg edema [48]. Additionally, portal vein compression near the porta hepatis has been reported to cause splenomegaly and portal hypertension [41]. Hepatic artery pseudoaneurysm is a rare, but
serious complication of ALA that results from erosion of the arterial wall by an aggressive abscess[83].

**Concurrent Colitis and Perforations**

Although diarrhea is found in only 15 to 30% of patients with ALA, concurrent colonic ulcers are detected in approximately 50% of patients with ALA on colonoscopy [17,57,84,85]. The colonic lesions on colonoscopy appear as small discrete ulcers in the cecum or ascending colon. Approximately 70% of the ulcers are localized to cecum and contiguous involvement of appendix (amebic typhlo-appendicitis) is common [10]. Because the ulcers are usually small and localized, symptoms related to colitis are mild. In severe cases, however, other segments may also be involved or there may be cecal perforations. Furthermore, the severity of colitis seems to parallel the severity of abscesses. Recently, Premkumar et al, in a study of 52 patients with ALA, reported bleeding and large ileocecal ulcers in the majority of their patients; most synchronous ALAs in this series had aggressive clinical and imaging features [85]. In an autopsy study of 76 patients with fatal ALA, Aikat et al found a 62% incidence of colonic ulcers [42]. With multidetector CT, we have observed concurrent colitis in 28% of the patients, more frequently and possibly more severe in the patients with aggressive ALA than those with mild ALA. On CT, the colitis generally manifests as nonspecific bowel wall thickening (Figure 1)[10].

**MANAGEMENT: ROLE OF IMAGE-GUIDED PERCUTANEOUS DRAINAGE**

ALA, in most patients, is mild and responds promptly to medical therapy. The drug of choice for the treatment of ALA is metronidazole, a nitroimidazole, which is given at a dose of 750 mg orally or intravenously three times daily for seven to ten days [31]. This regime results in resolution of fever, toxemia, and pain in 80% of 90% of patients with uncomplicated ALA within 72 to 96 h of treatment [7]. The disease resolves without complications or without the need for any invasive procedures. This treatment is followed by a luminal agent (paromomycin or diloxanide furoate) to clear the luminal parasites.
Decision to perform drainage is based largely on the clinical grounds. Any symptomatic patient with persistent symptoms after four days of treatment requires drainage, regardless of the imaging findings. In the most common scenario of percutaneous drainage, the patients continue to have symptoms, primarily pain or tenderness in the right upper quadrant, despite completed medical therapy. In another clinical setting, early drainage is performed for acute aggressive abscesses to control the disease severity\textsuperscript{[10]}. Third clinical setting may be the patients in whom there is diagnostic uncertainty between ALA and pyogenic abscess. In such cases, most physicians prefer to drain the amebic abscesses considering them as a pyogenic abscess.

In addition to clinical criteria, imaging-based criteria for the use of drainage was formulated by De la Rey Nel et al\textsuperscript{[86]}. They recommended that abscesses with the following risk factors should be drained: abscesses $>10$ cm (because of their long healing time), abscesses located in the left lobe (because of the risk of rupture into the pericardium), and large superficial abscesses with thin rim (because of the risk of rupture). In this context, it must be emphasized that lack of a mature wall is also an important risk factor that must be considered while assessing rupture risk. Most intraperitoneal ruptures in our series occurred when the abscesses lacked a mature wall\textsuperscript{[10]}.

\textit{Needle aspiration vs catheter drainage}

Percutaneous drainage can be performed either by needle aspiration or catheter drainage under image guidance. Usually, sonographic guidance suffices for the placement of the catheters or needle into the abscess cavity\textsuperscript{[11]}. CT guidance may be required in some cases, particularly in thoracic complications. The success of the procedure is dependent on its effectiveness in evacuation of the amebic pus. Needle aspiration is a simple, less invasive technique and requires less expertise. However, it is not as effective as catheter drainage, and presents several disadvantages. It fails to evacuate the solid necrotic tissue, which usually chokes the needle lumen during aspiration. Since the tissue necrosis and its liquefaction is a dynamic process, not all tissue is completely liquid at the point of time of aspiration, and therefore, multiple
sessions are generally needed to achieve complete drainage. This practice is perhaps related to the most serious drawback of needle aspiration, i.e., bacterial superinfections. The reported rate of superinfections following needle aspirations is 15% [18]. Nevertheless, needle aspirations may be useful in the appropriate settings, such as when the abscesses are small (< 5 cm) and the content is completely liquefied. Another common scenario includes multiple abscesses, where smaller and more liquefied abscesses are aspirated using an 18G spinal needle, whereas the larger and partially necrotic abscesses are drained using catheters [11]. Several randomized controlled studies have demonstrated that catheter drainage offers a higher success rate (up to 100%) compared to needle aspiration, particularly when abscesses are larger than 5 cm [78,87-89]. Because of its obvious advantage of having a large bore, it evacuates the necrotic tissue efficiently. It has an additional advantage of being indwelling, which makes it more effective in clearing those abscesses that liquefy over a period of time.

**Percutaneous drainage in management of complications**

Although aspirations have been useful in management of refractory abscesses for several decades, free rupture with peritonitis was typically considered an indication of surgery. The reported mortality rate in the surgically treated patients was as high as 50% [90-91]. In the last three decades, a paradigm shift has been seen from surgical drainage to catheter drainage. All complications related to ALA are currently managed with percutaneous catheter drainage [11,19-21,92-94]. By using catheter drainage, we have achieved a success rate of 97%, without significant mortality [11]. Only the placement of multiple catheters, usually in multiple sessions, is required to drain the intraperitoneal fluid collections. Because the collections are sterile, the peritonitis is not as severe as those seen in cases of bowel perforations. Not only is the catheter drainage curative for the intraperitoneal rupture, it also effectively treats pleuropulmonary ruptures [11]. The drainage of pleural fluid collections may require CT guidance as the ultrasound has low sensitivity for pleuropulmonary pathology. Lung abscesses usually do not require drainage because of the presence of bronchial fistula, which provides natural drainage in most patients. Catheter drainage has also been proved to be excellent in
management of biliary communications. Agarwal et al evaluated 33 patients with refractory abscess, nine of the patients were found to have an abscess with intrabiliary communication, and all patients were successfully treated with prolonged catheter drainage (12 to 50 days). None of the patients required endoscopic placement of stents [22]. Endoscopic stenting or sphincterotomy, however, may be required to control bile leak prior to catheter removal when fistulous communication persists despite prolonged catheter drainage. Catheter drainage has also been shown to facilitate spontaneous healing of small arterial aneurysm resulting from amebic liver abscess [83].

**Surgical Management**

The role of surgical drainage in management of ALA has been reassessed because of the widespread use of radiologically guided drainage [95]. However, open drainage may be warranted in some cases where percutaneous drainage may fail to evacuate abscess content. Surgery may also be indicated in selected cases of intraperitoneal rupture with generalized peritonitis [96]. As an alternative to open surgical drainage, laparoscopic drainage can produce less morbidity and mortality [97].

**CONCLUSION**

Clinical and imaging features of ALA are variable and parallel to each other. Although the mild form of the disease is cured easily with antibiotics alone, the two other forms of the disease — acute aggressive and chronic indolent — often require percutaneous drainage. Most complications and mortality in ALA occur when it presents in its acute aggressive form. Imaging studies play a key role in identifying the different forms of the disease and assessing the complications. All complications, including free intraperitoneal ruptures, can be managed with percutaneous catheter drainage.
