Basic Study
Towards a standard diet-induced and biopsy-confirmed mouse model of non-alcoholic steatohepatitis: Impact of dietary fat source

Boland ML et al. Translational mouse model of non-alcoholic steatohepatitis

Michelle L Boland, Taylor S Cohen, David E Tabor, Fiona Fernandes, Andrey Tovchigrechko, Paul Warrener, Bret R Sellman, James L Trevaskis, Department of Cardiovascular, Renal and Metabolic Diseases, MedImmune, Gaithersburg, MD 20878, United States

Michelle L Boland, Denise Oró, Kirstine S Tølbøl, Sebastian T Thrane, Jens Christian Nielsen, Sanne S Veidal, Jacob Jelsing, Michael Feigh, Niels Vrang, Henrik H Hansen, Department of Pharmacology, Gubra, Hørsholm DK-2970, Denmark

Author contributions: Boland ML, Cohen TS, Warrener P, Sellman BR, Feigh M, Vrang N, Trevaskis JL, and Hansen HH designed and coordinated the study; Boland ML, Oró D, Tølbøl KS, Thrane ST, Nielsen JC, Tabor DE, and Fernandes F performed the experiments, acquired and analyzed data; Boland
ML, Cohen TS, Tabor DE, Fernandes F, Oró D, Tølbøl KS, Thrane ST, Nielsen JC, Tovchigrechko A, Veidal SS, Feigh M, Jelsing J, Vrang N, Trevaskis JL, and Hansen HH interpreted the data; Boland ML, Jelsing, Trevaskis JL, and Hansen HH wrote the manuscript; all authors approved the final version of the article.

Abstract

BACKGROUND

The trans-fat containing amylin liver non-alcoholic steatohepatitis (NASH) (AMLN) diet has been extensively validated in C57BL/6J mice with or without the Lep<sup>ob</sup>/Lep<sup>ob</sup> (ob/ob) mutation in the leptin gene for reliably inducing metabolic and liver histopathological changes recapitulating hallmarks of NASH. Due to a recent ban on trans-fats as food additive, there is a marked need for developing a new diet capable of promoting a compatible level of disease in ob/ob and C57BL/6J mice.

AIM

To develop a biopsy-confirmed mouse model of NASH based on an obesogenic diet with trans-fat substituted by saturated fat.

METHODS

Male ob/ob mice were fed AMLN diet or a modified AMLN diet with trans-fat (Primex shortening) substituted by equivalent amounts of palm oil [Gubra amylin NASH, (GAN) diet] for 8, 12 and 16 wk. C57BL/6J mice were fed the same diets for 28 wk. AMLN and GAN diets had similar caloric content (40% fat kcal), fructose (22%) and cholesterol (2%) level.

RESULTS

The GAN diet was more obesogenic compared to the AMLN diet and impaired glucose tolerance. Biopsy-confirmed steatosis, lobular inflammation, hepatocyte ballooning, fibrotic liver lesions and hepatic transcriptome changes were similar in ob/ob mice fed the GAN or AMLN diet. C57BL/6J mice developed a mild to moderate fibrotic NASH phenotype when fed the same diets.

CONCLUSION
Substitution of Primex with palm oil promotes a similar phenotype of biopsy-confirmed NASH in ob/ob and C57BL/6J mice, making GAN diet-induced obese mouse models suitable for characterizing novel NASH treatments.

**Key words:** Non-alcoholic steatohepatitis; High-fat diet; Mouse model; Histopathology; Fibrosis; Liver biopsy; Liver transcriptome

**Core tip:** The trans-fat containing amylin liver non-alcoholic steatohepatitis (NASH) (AMLN) diet has been extensively validated in mice for reliably inducing metabolic and liver histopathological changes recapitulating hallmarks of NASH. A recent ban on trans-fats as food additive prompted the development of a new diet with similar disease-inducing properties as the AMLN diet. Here, we introduce a trans-fat-free diet high in palm oil (Gubra amylin NASH, GAN diet) that promotes a highly similar phenotype of biopsy-confirmed fibrotic NASH in both ob/ob and C57BL/6J mice, highlighting the suitability of GAN diet-induced obese mouse models of biopsy-confirmed NASH for the characterization of novel drug therapies for NASH.
INTRODUCTION

Liver-related complications have in recent years become widely recognized as among the most prevalent co-morbidities in obesity and diabetes. Non-alcoholic steatohepatitis (NASH) is the most severe form of non-alcoholic fatty liver disease (NAFLD), an umbrella term for a range of medical conditions with hepatic steatosis unrelated to significant alcohol consumption, use of steatogenic medication or hereditary disorders[1]. Notably, presence of obesity, dyslipidemia and type 2 diabetes constitutes the strongest risk factors for NASH[2,3], which has led to the concept that NASH represents the hepatic manifestation of the metabolic syndrome[4,5]. Liver biopsies represents the gold standard method for diagnosing and grading of NASH[6]. In NASH, lobular inflammation and liver cell damage (hepatocyte ballooning) are mandatory histopathological features in addition to steatosis[7]. Notably, the vast majority of patients with NAFLD across the disease spectrum is asymptomatic with an unpredictable onset of NASH and with rates of fibrosis progression not linear with time. As a result, disease severity varies considerably among affected NASH patients and may progress to cirrhosis undiagnosed[8,9]. Among the various histology-based scoring systems applied, the NAFLD activity scoring (NAS) system is the most prevalent diagnostic tool for defining NASH and assess disease activity[10]. While not initially designed for the specific purpose of assessing therapeutic drug efficacy, the NAS system is now the most widely used scoring system in clinical trials for NASH.

The conspicuous clustering of obesity, diabetes and metabolic comorbidities in NASH patients underscores that overnutrition and dietary factors play an important role in the transition from mild NAFLD to manifest NASH. The pathogenesis of NASH is complex and multifactorial, implicating multiple parallel and converging signaling pathways. Current ‘multiple-hit’ hypotheses consider several insults acting sequentially or together on a background of genetical predisposition to promote NAFLD and transition to NASH. Early pathogenic events are associated with hepatic triglyceride
accumulation as result of excessive caloric intake, stimulation of hepatic de novo lipogenesis secondary to insulin resistance, and impaired free fatty acid clearance. Increasing triglyceride levels in hepatocytes can lead to overproduction of reactive lipid metabolites (lipotoxicity) that eventually override hepatic adaptive and regenerative mechanisms,[11-13] triggering detrimental immune cell responses with downstream activation of resident fibrogenic myofibroblasts that produce and secrete collagens.[13-15]. In the event of continuing insufficient regenerative responses, progressive extracellular matrix deposition may result in excessive fibrotic liver damage and hepatocellular cancer.

The emergence of these theories has played an important role in the development of animal models of NASH with more reproducible and robust liver histopathology. Diet-induced obese (DIO) mice fed Western diets are attractive as they recapitulate the natural history of NASH.[16]. In addition, the human NAS system largely correlates with similar histopathologic lesions in these models,[17], which makes obese mouse models of NASH increasingly employed in preclinical NASH research. Conventional obesogenic high-fat diets promote dyslipidemia, fatty liver, and mild-stage NASH without appreciable fibrosis in rodents.[16]. Hence, additional dietary stimuli (‘hits’) are therefore applied to enhance the pro-fibrogenic properties of the high-fat diets employed in preclinical NASH research. Among the various dietary approaches, specific modifications in Western-type obesogenic diets have consistently been reported to promote fibrotic NASH in mice. Accordingly, C57BL/6J mice fed a high-fat/fructose diet supplemented with trans-fat and cholesterol (amylin liver NASH diet, i.e., AMLN diet[18]) develop manifest NASH, characterized by steatosis, lobular inflammation and hepatocyte ballooning. Notably, a significant proportion of C57BL/6J mice fed the AMLN diet (AMLN DIO-NASH mice) develop mild to moderate fibrosis following ≥ 26 wk of feeding.[18-23]. The hepatopathology is similar, but accentuated, in leptin-deficient C57BL6J-Lepob/Lepob (ob/ob) mice fed the AMLN diet, demonstrating a fibrotic NASH phenotype after ≥ 12 wk of feeding.[22,24-26]. The
two AMLN DOI models of NASH have been extensively characterized in pharmacology studies with employment of biopsy-confirmed histopathology for grading and staging of baseline liver pathology[23,24,27]. As in the clinic, DIO mouse models of NASH have unpredictable onset of disease with varying rates of progression. Consequently, any given cohort of DIO mice may represent all stages of NAFLD following long-term high-fat feeding[18,22,28,29]. This makes it imperative to control for inherently variable dynamics in NAFLD progression that could otherwise lead to misinterpretation of data obtained in longitudinal studies. Liver biopsy procedures have therefore recently been introduced to prevent bias and enable stringent within-subject analyses in both mice[18,22,23,27] and rats[30].

Addition of dietary trans-fats (also called trans-unsaturated fatty acids or trans fatty acids) has been reported to enhance the steatogenic and profibrotic properties of obesogenic diets in mice, including the AMLN diet[24] and variants thereof[21,31-33]. The underlying molecular mechanisms are not fully understood, but trans-fats may likely sensitize to the hepatotoxic effects of high-fat/carbohydrate diets by increasing insulin resistance, hepatic lipogenesis and oxidative stress[24,32,34-36]. A recent FDA ban on trans-fats as food additive[37], however, has prompted the development of a non-trans-fat Western diet capable of promoting metabolic and liver histopathological changes comparable to that afforded by the AMLN diet. The present study therefore aimed to develop and characterize a compatible biopsy-confirmed obese mouse model of NASH based on an isocaloric palmitic acid-enriched diet with a nutrient composition similar to the AMLN diet.

MATERIALS AND METHODS

Animals
Male ob/ob and C57BL/6J (C57) mice were from Jackson Laboratory (Bar Harbor, ME) or Janvier Labs (Le Genest Saint Isle, France), arrived at 5-8 wk of age and housed in a controlled environment (12 h light/dark cycle, 21 ± 2 °C, humidity 50 ± 10%). Mice were stratified and randomized to individual
diet groups according to baseline body weight and had ad libitum access to tap water and chow (2018 Teklad Rodent Diet, Envigo, Madison, WI; Altromin 1324, Brogaarden, Hoersholm, Denmark), AMLN diet (40 kcal-% fat (of these 22% trans-fat and 26% saturated fatty acids by weight), 22% fructose, 10% sucrose, 2% cholesterol; D09100301, Research Diets, New Brunswick, NJ, United States)\textsuperscript{[22,24]} or Gubra amylin NASH diet [GAN diet; 40 kcal-% fat (of these 0% trans-fat and 46% saturated fatty acids by weight), 22% fructose, 10% sucrose, 2% cholesterol; D09100310, Research Diets]. Mice were fed chow, AMLN or GAN diet for 8, 12 or 16 wk (ob/ob) and 28 wk (C57BL/6j), respectively. The study was approved by The Institutional Animal Care and Use Committee at MedImmune (Gaitherburg, MD, United States) and The Danish Animal Experiments Inspectorate (license 2013-15-2934-00784) in accordance with internationally accepted principles for the use of laboratory animals.

**Body weight, body composition and liver fat mass**

Body weight was monitored weekly. Whole-body fat mass was analyzed at week 8, 12 and 16 of the feeding period by non-invasive EchoMRI scanning using EchoMRI-900 (EchoMRI, Houston, TX, United States). During the scanning procedure, mice were placed in a restrainer for 90-120 s.

**Intraperitoneal glucose tolerance test**

An intraperitoneal glucose tolerance test (ipGTT) was performed in week 7 of the feeding period. Animals were fasted for 4 h prior to administration of the glucose bolus (1.5 g/kg). Cages were changed at the time of fasting. At $t = 0$, C57 and ob/ob mice received a bolus of glucose by intraperitoneal injection (5 mL/kg). Blood samples were collected from the tail vein and blood glucose was measured at time points $t = 0, 15, 30, 45, 60, 90$ and 120 min after the glucose bolus. Mice were re-fed after the last blood sampling.

**Biochemical analyses**
Biochemical analyses were performed as reported previously\cite{22,26}. Terminal plasma samples from fed animals were assayed for alanine aminotransferase (ALT), aspartate aminotransferase (AST), total triglycerides (TG) and total cholesterol. Total liver lipid mass was determined using a Bruker LF-90 minispec system (Bruker Biospin Corporation, Billerica, MA, United States) and expressed relative (%) to total liver weight.

Liver biopsy
A separate cohort of ob/ob mice were fed AMLN or GAN diet for 9 wk before a liver biopsy procedure was applied as described in detail previously\cite{22}. On the surgery day, mice were anesthetized with isoflurane (2%-3%, in 100% oxygen), a small abdominal incision in the midline was made, and the left lateral lobe of the liver was exposed. A cone-shaped wedge of liver tissue (50-100 mg) was excised from the distal part of the lobe. The cut surface of the liver was closed by electrosurgical bipolar coagulation using an electrosurgical unit (ERBE VIO 100C, ERBE, Marietta, GA, United States). The liver was returned to the abdominal cavity, the abdominal wall was sutured and skin stapled. Carprofen (5 mg/kg, i.p.) was administered at the time of surgery and at post-operative day one and two. After the procedure, animals were single-housed and kept on the respective diet for a total period of 16 wk.

Liver histology and digital image analysis
Biopsy and terminal liver samples (both from the left lateral lobe) were fixed overnight in 4% paraformaldehyde. Liver tissue was paraffin-embedded and sectioned (3 μm thickness). Sections were stained with hematoxylin-eosin (HE, Dako, Glostrup, Denmark), Picro-Sirius red (Sigma-Aldrich, Broendby, Denmark), anti-galectin-3 (cat. 125402, Biolegend, San Diego, CA, United States), or anti-type I collagen (Col1a1; cat. 1310-01, Southern Biotech, Birmingham, AL, United States) using standard procedures\cite{22,23}. The NAS and fibrosis staging system was applied to liver pre-biopsies and terminal samples for scoring of steatosis, lobular inflammation, hepatocyte ballooning,
and fibrosis outlined by Kleiner et al\textsuperscript{[10]}. Quantitative histomorphometry was analyzed using digital imaging software (VIS Software, Visiopharm, Hørsholm, Denmark)\textsuperscript{[22,23]}. Proportional (fractional) areas of liver fat (HE-staining), galectin-3 and Col1a1 were expressed relative to total sectional area. All histological assessments were performed by histologists blinded to the experimental groups.

**RNA sequencing**

Liver transcriptome analysis was performed by RNA sequencing on RNA extracts from terminal liver samples (15 mg fresh tissue), as described in detail elsewhere\textsuperscript{[22,23]}. The RNA quantity was measured using Qubit\textsuperscript{®} (Thermo Scientific, Eugene, OR, United States). The RNA quality was determined using a bioanalyzer with RNA 6000 Nano kit (Agilent, Waldbronn, Germany). RNA sequence libraries were prepared with NeoPrep (Illumina, San Diego, CA, United States) using Illumina TruSeq stranded mRNA Library kit for NeoPrep (Illumina, San Diego, CA, United States) and sequenced on the NextSeq 500 (Illumina, San Diego, CA, United States) with NSQ 500 hi-Output KT v2 (75 CYS, Illumina, San Diego, CA, United States). Reads were aligned to the GRCm38 v84 Ensembl Mus musculus genome using STAR v.2.5.2a with default parameters\textsuperscript{[38]}. Differential gene expression analysis was performed with DEseq2\textsuperscript{37}. Genes with a Benjamini and Hochberg adjusted $P \leq 0.05$ (5% false discovery rate, FDR) were regarded as statistically significantly regulated. The Reactome pathway database\textsuperscript{[39]} was used as gene annotation in a gene set analysis using the R package PIANO v.1.18.1\textsuperscript{[40]}, with the Stouffer method and Benjamini-Hochberg adjusted $P$ values (FDR < 0.01).

**Statistical analyses**

Except for RNA sequencing, data were analyzed using GraphPad Prism v7.03 software (GraphPad, La Jolla, CA, United States). All results are shown as mean ± standard error of mean. A two-way ANOVA with Tukey's multiple comparisons test was performed for body weight and quantitative
histological analyses. A one-way ANOVA with Dunnett’s post-hoc test was used for all other parameters. A $P$ value < 0.05 was considered statistically significant.

RESULTS

Metabolic changes in ob/ob mice fed GAN or AMLN diet for up to 16 wk

The temporal progression of metabolic deficits was determined in ob/ob mice fed the GAN (GAN ob/ob-NASH) or AMLN (AMLN ob/ob-NASH) diet for up to 16 wk. Body weight curves were significantly different in GAN and AMLN ob/ob-NASH mice (overall $P < 0.001$, two-way ANOVA). Compared to the AMLN diet, the GAN diet induced greater body weight gain in ob/ob mice from diet week 7 and onwards (Figure 1A). Relative body weight gain over the 16-week feeding period was $141.6 \pm 2.9\%$ (GAN ob/ob-NASH) and $125.2 \pm 3.6\%$ (AMLN ob/ob-NASH). GAN-ob/ob mice displayed more pronounced increases in whole-body fat mass at all time points measured (Figure 1B). The GAN and AMLN diets promoted similar degree of hepatomegaly in ob/ob mice (Figure 1C). An ipGTT was performed in diet week 7 and demonstrated impaired glucose tolerance in GAN, but not AMLN, ob/ob-NASH mice compared to chow-fed C57 controls (Figure 1D and E). During the ipGTT, plasma insulin levels were equally elevated in GAN and AMLN ob/ob-NASH mice (Figure 1F). Plasma ALT and AST levels were significantly increased in GAN and AMLN ob/ob-NASH mice after 8 wk on the diet and did not change further during the 16-wk feeding period. The GAN and AMLN diets promoted a similar degree of hypercholesterolemia (diet week 8-16, $P < 0.05$) in ob/ob mice with slightly reduced TG levels (diet week 16, $P < 0.05$), as compared to chow-fed C57 mice (Table 1).

Terminal liver lipid levels in GAN and AMLN ob/ob-NASH mice were approximately 10-fold higher than that of age-matched C57 mice and were maximally elevated after 8 weeks of feeding (Table 1). In addition to metabolic changes, the gut microbiome composition in GAN and AMLN ob/ob mice was characterized by bacterial 16S rRNA gene sequencing performed on
serial fecal samples. The GAN and AMLN diets promoted similar taxonomic shifts compared to baseline (chow feeding). The structural modulation of the gut microbiota was largely manifest two weeks after the change to GAN or AMLN diet, being slightly more accentuated following 16 wk of feeding (Supplemental Figure 1). Compared to baseline, the changes in microbiome composition in GAN and AMLN ob/ob mice was mainly driven by increases in the relative abundance of Akkermansia, Bacteroides and Parasutterella with reciprocal decreases in Clostridiales and Porphyromonadaceae. Consistently lowered relative abundance of Lactobacillus was also observed in GAN ob/ob-NASH mice.

Biopsy-confirmed progression of liver histopathology in ob/ob mice fed GAN or AMLN diet for 16 wk

Liver histopathological changes in GAN ob/ob mice were assessed in ob/ob mice fed GAN or AMLN diet for 16 wk (n = 8-10 per group). A liver biopsy was sampled after 9 wk on the respective diet for within-subject analysis of disease progression. Representative histological stainings are shown in Figure 2A. Comparable changes in composite NAS and fibrosis scores from feeding week 9 to 16 were observed in GAN ob/ob and AMLN ob/ob mice (Figure 2B). At feeding week 9, GAN ob/ob and AMLN ob/ob mice showed mild-to-moderate fibrosis (F1-F2) with an equal distribution of mice progressing in fibrosis severity. A major proportion of GAN or AMLN diet fed ob/ob mice demonstrated moderate fibrosis after 16 weeks of feeding (Figure 2C). Individual pre-biopsy and terminal histopathological scores on steatosis, lobular inflammation and hepatocyte ballooning are indicated in Supplemental Figure 2. Steatosis severity was severe (score 3) and sustained after 9 weeks of feeding in both GAN and AMLN ob/ob-NASH mice. Both diets induced moderate-grade (score 2) lobular inflammation in almost all ob/ob mice without significant changes from feeding week 9 to 16. The rate of hepatocyte ballooning was low in ob/ob mice fed the GAN or AMLN diet for 9 weeks, however, increased during the remainder of the feeding period.
Hepatocyte ballooning did not progress beyond grade 1 in ob/ob mice. Terminal quantitative histopathological changes were also similar in ob/ob mice fed the GAN or AMLN diet, as indicated by morphometric analyses of steatosis, inflammation and Col1a1 (Figure 3).

**Liver transcriptome changes in ob/ob mice fed AMLN or GAN diet for 16 wk**

To characterize the effect of 16-week feeding on global liver gene expression, the transcriptome of GAN and AMLN ob/ob-NASH mice vs. chow-fed C57 mice were analyzed by RNA sequencing. To assess the overall similarity of the individual transcriptome samples, a principal component analysis (PCA) was performed. The primary PCA (accounting for the major variability in the data set) yielded conspicuous clustering of transcriptome samples from GAN and AMLN ob/ob-NASH mice, being clearly separated from chow-fed C57 controls (Figure 4A), indicating that the two NASH-promoting diets overall promoted substantial, however highly similar, alterations in liver global gene signatures of ob/ob mice. In accordance, a total pool of 9725 and 9760 differentially expressed genes (DEGs) were identified in GAN and AMLN ob/ob-NASH mice, respectively, with virtually all regulated genes being shared in the two ob/ob-NASH groups (Figure 4B). For initial evaluation of the DEGs identified, we probed for candidate gene transcripts associated with NASH and fibrosis (see Supplemental Table 1). GAN and AMLN ob/ob-NASH mice showed significant and overlapping regulations of candidate genes (Figure 4C), particularly associated to modulated fatty acid synthesis (Fasn, Scd1), reduced fatty acid β-oxidation (Cpt-1), lowered triglyceride synthesis (Gpat4), reduced cholesterol synthesis (Hmgcr, Hmgcs1) and transport (ApoCIII, Ldlr, Lrp1, Scarb1); impaired insulin (Akt, Irs1, Irs2) and FXR (Cyp7a1, Cyp8b1, Ostb) signaling; enhanced monocyte differentiation/recruitment (Ccr1, Ccr2, Cdl4, Cdl8, Cdl68, Cdl1a, Cdl1a, Mac-2, Mcp-1), pro-inflammatory signaling (Nfkb, P38, Tgfrb, Tnfa); inflammasome (Ipaf, Nlrp1b, Nlrp3, Tlr4) and pro-apoptotic activity (Casp-8, Rip-1, Rip-3), and enhanced extracellular matrix (ECM) reorganization (a-Sma, Col1a1, Col1a2, Col3a1, Col5a1/2/3, Col6a1/2/3, Mmp2,
Mmp13, Timp1/2/3). When performing a group-wise comparison of global gene expression profiles in GAN vs. AMLN ob/ob mice, liver transcriptome signatures were distinguished by only nine DEGs (Ces3b, Cfhr1, Cyp1a1, Cyp2f2, Gm4788, Keg1, Serpina3k, Ugt1a9, Ugt2a3). To obtain further resolution of the liver transcriptome changes in GAN vs. AMLN ob/ob-NASH mice vs. chow-fed C57 controls, a gene set enrichment analysis was subsequently conducted. The Reactome gene annotation analysis identified several disease-relevant biological pathways significantly enriched in both GAN and AMLN ob/ob-NASH mice. Notably, all significantly enriched pathways were completely overlapping between GAN and AMLN ob/ob-NASH mice (Figure 4D).

Liver histopathology in C57 mice fed GAN or AMLN diet for 28 wk
To investigate liver histological changes in wild-type mice, C57 mice were fed chow (n = 15), GAN (n = 30) or AMLN (n = 30) diet for 28 wk. Histopathological scores and proportionate area of Col1a1 are shown in Figure 5. GAN and AMLN diets were both highly obesogenic in C57 (GAN DIO-NASH, AMLN DIO-NASH) mice. GAN DIO-NASH mice showed significantly higher endpoint body weight (46.0 ± 0.8 g) compared to AMLN DIO-NASH (40.6 ± 0.6 g, P < 0.001) and chow-fed C57 mice (30.7 ± 0.4 g, P < 0.001 vs GAN DIO-NASH and AMLN-DIO NASH mice). While age-matched chow-fed C57 mice displayed normal liver histology, GAN DIO-NASH mice developed severe steatosis (score 3, 30/30 mice) and moderate-to-severe lobular inflammation (score 0, 1/30 mice; score 1, 3/30 mice; score 2, 19/30 mice; score 3, 7/30 mice) upon 28 wk of feeding (Figure 5A and B). Hepatocyte ballooning was largely absent in GAN DIO-NASH mice (score 0, 26/30 mice; score 1, 4/30 mice, Figure 5C). Generally, a NAS of 5-6 was observed in GAN DIO-NASH mice (score 3, 1/30 mice; score 4, 3/30 mice; score 5, 17/30 mice; score 6, 7/30 mice; score 7, 2/30 mice, Figure 5D). Fibrosis was typically mild to moderate in GAN DIO-NASH mice (F0, 1/30 mice; F1, 10/30 mice; F2, 18/30 mice; F3, 1/30 mice), see Figure 5E. AMLN
DIO-NASH mice showed a liver histological phenotype very similar to GAN DIO-NASH mice, as indicated by severe steatosis (score 3, 30/30 mice), moderate to severe lobular inflammation (score 0, 1/30 mice; score 1, 3/30 mice; score 2, 19/30 mice; score 3, 7/30 mice), inconsistent hepatocyte ballooning (score 0, 17/30 mice; score 1, 13/30 mice), and mild-to-moderate fibrosis (F0, 3/30 mice; F1, 4/30 mice; F2, 23/30 mice; F3, 0/30 mice). In addition, Col1a1 proportionate areas were increased to a similar degree in GAN and AMLN DIO-NASH mice, as compared to chow-fed C57 mice, see Figure 5F.

DISCUSSION

The AMLN DIO-NASH and ob/ob-NASH mouse models have been extensively validated and characterized in an increasing number of pharmacology studies. Here, we compared the metabolic and liver histological phenotype in ob/ob mice fed the AMLN diet or a modified AMLN diet (GAN diet) with Primex shortening, a trans-fat containing food additive, substituted with equivalent amounts of palm oil. The GAN and AMLN diets promoted similar biopsy-confirmed liver lesions with hallmarks of fibrotic NASH in both ob/ob and C57 mice. Hence, the maintained NASH phenotype in both ob/ob and C57 mice indicates the utility of GAN DIO mouse models of biopsy-confirmed NASH for the preclinical characterization of novel drug therapies for NASH.

The composition of the AMLN diet, containing high levels of saturated fat, fructose, trans-fat and cholesterol, reflects dietary factors considered important in the pathogenesis of NAFLD/NASH. Accordingly, excess energy intake from dietary fat and simple sugars (Western diets) has been strongly linked to NAFLD/NASH[41,42]. In particular, increased consumption of saturated fats and fructose has been associated with the deleterious effects of intrahepatic lipid accumulation, enhanced lipogenesis, insulin resistance, hepatocyte oxidative stress and inflammation in NAFLD/NASH[43-47]. Although less well-characterized in NASH, trans-unsaturated fat
consumption and dietary cholesterol may sensitize to the hepatotoxic effects of excessive fat and fructose intake[31,32,48,49]. Because the FDA has recently imposed a ban on the use of trans-fat additives in foods, this prompted us to develop a compatible mouse model of NASH based on an obesogenic diet high in saturated fat and with a nutrient composition and caloric density similar to the AMLN diet.

The GAN and AMLN diets were both highly obesogenic in ob/ob mice. Notably, weight gain and adiposity were even more pronounced in mice fed the GAN diet. Other high-fat/trans-fat diets have been reported inducing slightly less weight gain in wild-type mice compared to trans-fat-free hypercaloric diets[36]. Although not specifically addressed in the present study, it may be speculated that substitution of trans-fat with palm oil led to improved diet palatability and/or fat absorption rates. This is also indirectly supported by the observation that hyperphagic ob/ob mice fed the AMLN diet attain slightly less weight gain compared to chow feeding[22,23]. Consistent with previous reports[22,24,27], the AMLN diet did not influence glucose homeostasis in ob/ob mice which contrasts findings of mild glucose intolerance in obese wild-type mice fed other high-fat/trans-fat diet types[31,36,50]. The AMLN diet has been reported to elevate endogenous glucose production in C57 mice[51], suggesting development of peripheral insulin resistance. As also C57 mice fed the AMLN diet maintain normal oral glucose tolerance[22,24], it may be speculated that glucoregulatory effects of trans-fats depend on the composition of trans-fat species in obesogenic diets. In contrast, GAN ob/ob-NASH mice displayed significantly impaired glucose tolerance compared to chow-fed C57 mice, indicating a more robust insulin-resistant phenotype in GAN ob/ob-NASH mice. Because insulin resistance is closely associated with NAFLD and is recognized as an important pathophysiological factor in the progression to NASH[52-54], this lends further support to the translatability of the GAN ob/ob-NASH mouse model. It should be noted that GAN and AMLN ob/ob-NASH mice both showed suppressed expression of hepatic genes related to lipid and glucose handling. This points to the possibility that
extrahepatic mechanisms contribute to impaired glucose handling in GAN ob/ob-NASH mice. GAN and AMLN ob/ob-NASH mice demonstrated similarly profound hyperinsulinemia, which argues for sustained pancreatic β-cell compensation in both models. Importantly, however, glucose intolerance in leptin-deficient ob/ob mice has been attributed to failure to suppress hepatic glucose production in conjunction with impaired muscle glucose uptake, likely precipitated by defective triglyceride handling in these tissues[55-57]. In addition, ob/ob mice show impaired glucose uptake in adipose tissues[58,59]. Although the present study did not specifically determine insulin sensitivity by hyperinsulinemic-euglycemic clamp techniques, the marked adipogenic properties of the GAN diet may therefore promote insulin resistance at both the hepatic and extrahepatic level to facilitate manifest glucose intolerance in GAN ob/ob-NASH mice.

Consistent with the obese phenotype in GAN and AMLN ob/ob-NASH mice, the two models demonstrated pronounced hepatomegaly and intrahepatic lipid accumulation. Development of hypercholesterolemia, but not hypertriglyceridemia, was also a shared feature in GAN and AMLN ob/ob-NASH mice, possibly attributed to suppressed hepatic triglyceride secretion, as high dietary cholesterol intake can downregulate hepatic cholesterol ester and lipoprotein synthesis[60,61]. This is supported by our finding of reduced expression of several hepatic genes involved in cholesterol synthesis and transport. Enhanced hepatic fat uptake combined with impaired capacity to secrete fatty acids may thus be important mechanisms leading to marked steatosis in GAN and AMLN ob/ob mice. Hepatic injury was suggested by increased levels of plasma transaminases in GAN and AMLN ob/ob mice, subsequently confirmed by liver histology. We have previously reported that ob/ob mice develop reliably manifest NASH when maintained on AMLN diet for a relatively short feeding period (≥ 12 wk). The AMLN ob/ob-NASH model is characterized by biopsy-confirmed severe hepatic steatosis, moderate to severe lobular inflammation, mild hepatocyte ballooning and fibrotic lesions increasing in severity with prolonged feeding periods[22,24-26], recapitulating
clinical histopathological criteria for the diagnosis of fibrosing NASH\textsuperscript{[7,62]}. Also, the AMLN ob/ob-NASH model has been extensively characterized in pharmacology studies\textsuperscript{[23-25,27]}. Notably, ob/ob mice fed the GAN and AMLN diet, respectively, developed a highly similar fibrotic NASH phenotype with comparable within-subject disease progression rates during the feeding period. Accordingly, GAN and AMLN-ob/ob-NASH mice demonstrated similar liver histopathology, as determined by both standard clinical histopathological scoring and imaging-based quantitative histological assessment of steatosis, inflammation and fibrosis.

The GAN and AMLN diets induced virtually identical hepatic transcriptome signatures with marked alterations in candidate genes associated with NAFLD/NASH. An unsupervised analysis for full-scale mapping and functional annotation of liver transcriptome signatures confirmed completely overlapping GAN and AMLN diet-induced hepatic signaling pathway perturbations with signatures of inefficient intrahepatic lipid and carbohydrate handling, stimulated immune cell activity, increased apoptotic activity, ECM remodeling and cell cycle modulation. In addition to suppressed transcription of genes associated with cholesterol metabolism (discussed above), a subset of genes involved in fatty acid catabolism (β-oxidation) and storage (triglyceride synthesis) were also downregulated. This could indirectly suggest free fatty acid overload and defective lipid compartmentation, which has been associated with hepatocyte cytotoxicity (lipotoxicity), inflammation and apoptosis in NASH\textsuperscript{[11-13]}. Also, increased immune activity and hepatocyte damage was supported by upregulation of genes involved in monocyte differentiation/recruitment, pro-inflammatory cytokine production, inflammasome activation and pro-apoptotic signaling. The significant upregulation of α-Sma, multiple collagen isoforms (Col1a1, Col1a2, Col3a1, Col5a1/2/3, Col6a1/2/3) and molecules involved in ECM reorganization (Mmp2, Mmp13, Timp1/2/3), suggests that hepatic collagen accumulation in GAN and AMLN ob/ob-NASH mice is a combined effect of stimulated fibrogenesis and altered balance between the activity of collagen-
degrading matrix metalloproteinases and tissue inhibitors of metalloproteinases.

The observation that the GAN and AMLN diets both promoted consistent fibrotic NASH in ob/ob mice indicates that palm oil supplementation fully compensated for the lack of trans-fat in the GAN diet. The extent of hepatic saturated fatty acid accumulation parallels disease severity in NAFLD/NASH patients[63], and inefficient disposal of saturated free fatty acids is considered hepatotoxic[64,65]. Specifically, the particularly high levels of palmitic acid in the GAN diet (37% of total fat by weight) compared to the AMLN diet (17% of total fat by weight) invites the possibility that this nutritional component played an integral role in the development and progression of liver pathology in GAN ob/ob-NASH mice. In support of this view, high palmitic acid (palmitate at physiological pH) levels in hepatocytes and non-parenchymal liver cells can trigger substantial lipotoxic damage through various mechanism associated with NASH pathology, including oxidative stress[66], endoplasmic reticulum stress[67], pro-apoptotic signaling[68] as well as Kupffer cell[69] and hepatic stellate cell activation[70]. In addition to direct cytotoxicity, hepatic palmitic acid overload can also promote hepatotoxic effects via increased formation palmitate-derived complex lipids, including ceramides[71]. Interestingly, long-term AMLN diet feeding has been reported to elevate hepatic levels of palmitate-containing ceramides in C57 mice, most likely due to incomplete mitochondrial fatty acid oxidation nutritional as result of nutritional overload[20].

Compared to AMLN ob/ob-NASH mice, longer AMLN diet feeding periods (≥ 26 wk) are required for inducing consistent fibrotic NASH in C57 mice[18,19,22,23], which is likely explained by hyperphagia-driven excessive AMLN diet intake in leptin-deficient ob/ob-NASH mice. A comparative study was therefore also performed in C57 mice fed the GAN or AMLN diet for 28 wk (DIO-NASH mice). Similar to ob/ob mice, C57 mice showed significantly greater weight gain when fed the GAN diet compared to AMLN diet. Histological assessments of biopsied liver specimens revealed highly
compatible liver lesions in GAN and AMLN DIO-NASH mice. Both models presented with manifest NASH (NAS ≥ 4), characterized by severe steatosis, moderate-to-severe lobular inflammation. In GAN DIO-NASH mice, fibrosis stage was mild to moderate with significantly increased proportionate area of Col1a1 compared to chow-fed C57 mice showing normal liver histology. Consistent with previously reported studies in AMLN DIO-NASH mice[23,72], hepatocyte ballooning was only detected in a subset of GAN and AMLN DIO-NASH mice. In addition to the GAN diet, other isocaloric variants of the AMLN diet were tested for the ability to induce a metabolic and NASH phenotype comparable to the AMLN diet. Compared to the GAN diet, ob/ob and C57 mice did not consistently develop fibrotic NASH when fed these diets, including diets supplemented with trans-fat from partially hydrogenated corn oil (Supplemental Table 2). As the trans-fatty acids (largely trans-oleic acid) in the AMLN diet are derived from partially hydrogenated soybean and palm oils, the differences in liver histopathology may therefore relate to the source of dietary fat used to prepare the partially hydrogenated vegetable oil.

We also characterized the gut microbiome composition in ob/ob mice fed the GAN and AMLN diet. GAN and AMLN ob/ob-NASH mice exhibited a similar gut microbiome signature, which further emphasizes the comparable phenotype in GAN and AMLN ob/ob-NASH mice. Both high-fat diets promoted sustained bacterial taxonomic shifts which were evident only two weeks after switching from chow feeding. Other high-fat diet feeding regimens have been reported to induce rapid gut microbiome structural changes in mice[73-75], suggesting that dietary fat played a major role in modulating gut bacterial communities in GAN and AMLN ob/ob-NASH mice. At the genus level, the microbiome signature in GAN and AMLN ob/ob-NASH mice was dominated by increased abundance of Bacteroides and Akkermansia paralleled by reductions in unclassified Porphyromonadaceae. Although various fecal microbiome profiles have been associated with NASH[76], recent studies have indicated increased Bacteroides[77-79] and reduced Porphyromonadaceae[80]
abundance in NASH patients compared to healthy control subjects. *Bacteroides* have a large number and diversity of genes encoding enzymes converting complex polysaccharides to short-chain fatty acids that serve as energy substrates and signaling molecules[81,82]. Increased energy harvest from bacterial degradation of dietary polysaccharides has been suggested to contribute to adiposity in *ob/ob* mice[83]. In addition, *Bacteroides* and *Akkermansia* include prominent mucosa-degrading species[84], which have been linked to modulation of gut barrier integrity and immune responses in obesity-associated diseases, including NASH[85,86]. It should be considered that high-fat diet feeding has been reported to promote similar gut microbiome signatures in obesity-prone and obesity-resistant mice, which signifies efficient gut ecosystem adaptations to dietary changes independent of the metabolic phenotype[87]. Given the early and stable changes in dominant gut bacterial genera following the shift from chow to GAN/AMLN diet feeding, it cannot be ruled out that microbial adaptive responses secondary to altered nutrient intake played a role in shaping the gut microbiome in GAN and AMLN *ob/ob* mice.

**CONCLUSION**

In conclusion, modification of the AMLN diet by substitution of Primex shortening with palm oil (GAN diet) resulted in a maintained NASH phenotype in both *ob/ob* and C57 mice. The GAN diet was more obesogenic than the AMLN diet in both *ob/ob* and C57 mice and impaired glucose intolerance in *ob/ob* mice. Hence, the clear metabolic and histopathological hallmarks of NASH in *ob/ob* and C57 mice fed the GAN diet highlights the suitability of these mouse model for characterizing novel drug therapies for NASH.

**ARTICLE HIGHLIGHTS**

*Research background*
Non-alcoholic steatohepatitis (NASH) is an obesity-associated liver disease with marked unmet medical need. Various diet-induced obese animal models of NASH have been employed in preclinical research, target discovery and drug development. The trans-fat containing amylin liver NASH (AMLN) diet, high in fat, fructose and cholesterol, has been widely used in ob/ob and C57BL/6J mice for reliably inducing metabolic and liver histopathological changes recapitulating hallmarks of NASH.

Research motivation
A recent ban on trans-fats as food additive has prompted the development of a trans-fat free high-fat diet capable of promoting a compatible level of disease in ob/ob and C57BL/6J mice.

Research objectives
The present study aimed to develop and characterize a liver biopsy-confirmed obese mouse model of NASH based on an isocaloric palmitic acid-enriched diet with a nutrient composition similar to the AMLN diet.

Research methods
Male ob/ob mice were fed AMLN diet or a modified AMLN diet with trans-fat (Primex shortening) substituted by equivalent amounts of palm oil [Gubra Amylin NASH, (GAN) diet] for 8, 12 and 16 wk. In addition, C57BL/6J mice were fed AMLN or GAN diet for 28 wk. AMLN and GAN diets were isocaloric (40% fat kcal; 10% sucrose, 22% fructose, 2% cholesterol). Disease phenotyping included metabolic, liver biochemical/histopathological/transcriptomics as well as gut microbiome analyses.

Research results
In ob/ob mice, the GAN diet was more obesogenic and adipogenic compared to the AMLN diet. Whereas the GAN diet promoted impaired oral glucose
tolerance in \textit{ob/ob} mice, the AMLN diet had no effect on glucose regulation. The GAN and AMLN diets induced similar severity of liver biopsy-confirmed steatosis, lobular inflammation, hepatocyte ballooning and fibrotic lesions. Also, hepatic transcriptome and gut microbiome changes were similar in \textit{ob/ob} mice fed the GAN and AMLN diet. Also, C57BL/6J mice fed the GAN and AMLN developed a similar histological phenotype of mild to moderate fibrotic NASH.

\textit{Research conclusions}
Substitution of trans-fat (Primex in the AMLN diet) with saturated fat (palm oil in the GAN diet) promotes a consistent phenotype of biopsy-confirmed fibrotic NASH in both \textit{ob/ob} and C57BL/6J mice.

\textit{Research perspectives}
GAN diet-based \textit{ob/ob} and C57BL/6J mouse models of biopsy-confirmed NASH are applicable for preclinical characterization of novel NASH treatments.
