Observational Study
Assessment of resting energy expenditure in patients with cirrhosis

Shaiane Ferreira, Cláudio Augusto Marroni, Jessica Taina Stein, Roberta Rayn, Ana Cristhina Henz, Natália P Schimidt, Randhall B Carteri, Sabrina Alves Fernandes

Abstract
BACKGROUND
Malnutrition affects 20 to 50% of patients with cirrhosis. It may be associated with serious complications and has a direct impact on prognosis. Resting energy expenditure (REE) is an important parameter to guide the optimization of therapy and recovery of nutritional status in patients with cirrhosis. However, the REE of patients with cirrhosis is still unclear, casting doubt upon the optimal nutritional management approach.

AIM
Identify the best method that predicts the REE of cirrhotic patients, using indirect calorimetry as the gold standard.

METHODS
Observational study of 90 patients with cirrhosis. REE was assessed by IC, BIA, and predictive formulas which were compared using Bland-Altman plots and the Student’s t-test.

RESULTS
REE values measured by IC (1607.72 ± 257.4 kcal) differed significantly from those determined by all other methods (BIA, 1790.48 ± 352.1 kcal; Harris & Benedict equation, 2373.54 ± 254.9 kcal; IOM equation, 1648.95 ± 185.6 kcal; Cunningham equation, 1764.29 ± 246.2 kcal), except the FAO/WHO/UNU (1616.07 ± 214.6 kcal) and McArdle et al. (1611.30 ± 241.8 kcal) equations. We found no significant association when comparing IC and 24-h dietary recall at different Child-Pugh classes of cirrhosis.

CONCLUSION

IOM and FAO / WHO / UNU showed the best agreement with the CI. These results indicate a possibility of different tools for the clinical practice on cirrhotic patients.

INTRODUCTION

The liver plays a key role in maintaining homeostasis and is the fundamental site of the metabolism of nutrients and other exogenous substances. Liver cirrhosis is the final stage of a chronic disease characterized by a process of disorganization in the lobular and vascular architecture of the liver, with fibrosis and diffuse nodular formation[1]. Importantly, it is estimated that there are 1.5 billion people diagnosed with chronic liver diseases, with an age-standardized incidence rate of 27.7 / 100,000 for cirrhosis in these patients[2]. Patients with cirrhosis, regardless of etiology, commonly present malnutrition, resulting in a significant imbalance in energy metabolism that negatively impacts their prognosis and their quality of life[3-5]. In this context, it is well established that cirrhotic patients benefit from improvements in dietary habits and nutritional interventions, and adequate dietary prescription depends on the precision of the protocols for energy requirement estimation.

The resting metabolic rate (RMR) reflects the energy required to maintain physiological processes, representing approximately 60 to 70% of the total daily energy requirement, whilst hepatic tissue metabolism accounts for almost 20% of the Resting Metabolic Rate in most patients[6,7]. Resting Metabolic Rate (RMR) is influenced by
different aspects of body composition, which could be drastically changed in the cirrhotic patient, due to hypercatabolism which is proportional to the disease progression\textsuperscript{8}. Different studies show that protein degradation is measured by increased oxygen consumption through indirect calorimetry, where an increase in resting energy expenditure (REE) is observed in 35\% of people with cirrhosis compared to the healthy population\textsuperscript{9-11}. This conflict could be explained by several confounding factors, such as the use of medication, the patient’s body composition, and the presence of comorbidities\textsuperscript{12}. However, current literature is still conflicting regarding the relationship between cirrhosis progression and RMR alterations. Some studies have reported an increase in REE compared to the healthy population\textsuperscript{13,14} while others have reported a decrease in REE\textsuperscript{15,16}. Therefore, since the nutritional prescription is crucial to mitigate the progression of liver malfunction and/or alleviate complications characteristic of cirrhosis appropriate estimation of patients' energy requirements is vital.

Indirect calorimetry is the most reliable method to estimate the resting metabolic rate, whilst it is expensive, time-consuming, and requires trained personnel and specific apparatus\textsuperscript{17}. Alternatively, several predictive equations were developed to estimate the REE using specific individual characteristics\textsuperscript{18}. Although most of the equations were developed in different populations, their accuracy in clinical practice is widely variable, albeit is a feasible method for RMR estimation when the proper equation for the individual is applied\textsuperscript{18}.

Currently, there is still no predictive equation considered the most accurate for cirrhotic patients. So much so that in the meta-analysis by Eslamparast T. \textit{et al.}, when analyzing 17 articles on the estimation of RMR in cirrhotic patients, which compare indirect calorimetry with different predictive formulas, they observe that the RMR values are underestimated, especially in males and in the western population. Furthermore, there are insufficient data regarding the value of RMR according to the severity of chronic liver disease\textsuperscript{19}. 
Noteworthy, miscalculation of REE in patients with cirrhosis can lead to inaccurate or inappropriate therapeutic management, worsening symptoms such as anorexia, dysgeusia, early satiety, nausea, and vomiting (especially in the presence of hepatic encephalopathy), and may potentiate adverse drug reactions. Within this context, the objective of the present study is to determine the REE of patients with cirrhosis by indirect calorimetry (IC) and compare the values thus obtained to those estimated by bioelectrical impedance analysis (BIA) and common predictive equations, in order to identify a reliable method for calculating energy expenditure applicable in clinical practice.

MATERIALS AND METHODS
This was an observational study. We included 90 patients who were receiving clinical management of liver cirrhosis at the Outpatient Gastroenterology and Liver Transplantation Clinics of Santa Casa de Misericórdia de Porto Alegre, Rio Grande do Sul, Brazil, from March 2017 to July 2018. All patients included in this study agreed to participate and provided written informed consent. The study protocol was approved by the Research Ethics Committees of Santa Casa de Misericórdia de Porto Alegre with opinion number 2.387.800. Sample size calculation was based on a previous study by Teramoto et al which compared measured and predicted energy expenditure in patients with cirrhosis. Considering a statistical power of 80% and a significance level of 5%, the minimum sample size was estimated at 90 patients.

Adult patients (age 18 years or older) of both sexes with cirrhosis of the liver were eligible for inclusion. Patients on enteral feeding were excluded, as were those with amputation of any limb, those unable to complete the proposed evaluations (e.g., those who reported discomfort during IC, who could not remain in position, or who had a pacemaker which precluded BIA). Data from the electronic medical records of the patients, related to the diagnosis, staging by the Child-Pugh score, age, and sex of the participants were collected. The diagnosis of cirrhosis was made by clinical, laboratory,
imaging, and/or, eventually, liver biopsy in accordance with the hospital liver transplant group standards[12].

Current body weight was measured on a calibrated Filizola® anthropometric scale (precision 0.1 kg). Height was measured with a wall-mounted stadiometer, with the patient standing upright and barefoot. Body mass index (BMI) was calculated as (BMI = weight (kg) / [height (cm)]²) and classified according to the World Health Organization curves[23].

Bioelectrical impedance analysis (BIA) was performed as described elsewhere using a Biodynamics® model 450 BIA device (current 800 µA, frequency 50 kHz), with electrodes placed on the hand/wrist and foot/ankle.

Indirect calorimetry (IC) was performed by the same investigator (SF), using a Korr MetaCheck™ calorimeter. The assessment was begun after a minimum of 4 h and a 30-minute rest. Measurement was performed with the patient perfectly still in the supine position, for 10 to 30 minutes, wearing a rigid face mask. The formula described by Weir (14) was used to calculate REE during the most stable period of analysis, based on O₂ consumption (VO₂), CO₂ output (VCO₂), and urine urea nitrogen (UUN), as follows: REE = [3.9(VO₂)] + [1.1(VCO₂)][24].

Table 1 describes the energy expenditure predictive equations used in the study: BIA - Based on Grande & Keys[25]; Cunningham[26]; Harris and Benedict[27]; Food and Agriculture Organization of the United Nations, World Health Organization and United Nations University (FAO/WHO/UNU)[23]; Institute of Medicine[28]; McArdle[29]; and Mifflin[30].

Statistical analysis
Quantitative variables were expressed as mean and standard deviation, and categorical variables, as absolute and relative frequencies. The equations were compared with indirect calorimetry using the Bland-Altman method[31], and also the Student’s t-test for paired samples. The Student’s t-test for paired samples was also used for comparison between IC and 24h dietary recall findings. The correlation between BMI and IC was assessed by Pearson’s correlation coefficient. Analysis of variance (ANOVA) with
Tukey’s post-hoc test was used for comparison of mean 24h dietary recall and REE-IC according to Child-Pugh class. The significance level was set at 5% ($p<0.05$). All analyses were performed in PASW Statistics, Version 18.0.

**RESULTS**

Ninety patients, with a mean age of 57.1 (±9.3) years, were assessed. Of these, 52 (57.8%) were male. The clinical profile of the sample is described in Table 2.

Table 3 shows the values of REE in kilocalories, measured with IC and predictive methods. The mean REE measured by IC was 1607.72 ± 257.4. A correlation between REE measured by IC and muscle mass in kilograms ($r^2 = 0.353$, $p = 0.001$) was also found. Also, the IC values were not different between patients classified in groups in accordance with their Child-Pugh scores ($p = 0.885$). Although the IC values showed a positive correlation with predictive methods, the IC values were significantly different when compared to predictive methods, except for the McArdle and FAO/WHO/UNU predictive equations.

As shown in Figure 1, we found differences in agreement between IC and the predictive methods. The best agreement was found between IC and the IOM equation, followed by FAO/WHO/UNU and McArdle equations. The agreement between IC and BIA was below 10% of the mean difference. The Harris and Benedict and the Mifflin equations showed less agreement with the IC values. The ANOVA analysis showed no differences of IC or REE estimated by different methods when patients were grouped by their Child-Pugh scores (data not showed).

**DISCUSSION**

The present study aimed to determine the REE of patients with cirrhosis by indirect calorimetry (IC) and compare the values thus obtained to those estimated by bioelectrical impedance analysis (BIA) and common predictive equations. The IOM and the FAO/WHO/UNU equation showed the best agreement with IC, whilst the McArdle and BIA could also be considered appropriate for REE estimation.
The present study evaluated 90 patients, with a mean age of 57 (± 9.3) years, which is close to previously reported[32] whilst the male predominance of the sample is also consistent with prior work by Tajika et al[51] and Wilkens Knudsen et al[53]. Regarding Child-Pugh classification, our sample was homogeneous, with 33 patients in class A, 36 in class B, and 21 patients identified as class C; this proportion differs from that reported by Qing-Hua Meng, where 60% of patients were Child-Pugh A and only 8 were class C[34]. Regarding nutritional status, the mean BMI of patients in our study was 28.6 ± 5.6 kg/m², which would classify them as overweight[23]. This result is in line with Brazilian studies of patients with cirrhosis which confirmed the same classification[5,35]. Like Fernandes et al[3], we did not find BMI to be a reliable method of estimating nutritional status in this population, due to the distortion of body weight inherent to the underlying disorder. Strikingly, we did not identify a correlation between BMI and REE, albeit we report a correlation between REE and muscle mass (in kilograms).

IC is considered by many researchers as the gold standard for measuring REE. It is a non-invasive method, capable of measuring basal energy expenditure by means of gas exchange, thus ensuring greater precision in measurement[35-37]. In our study, the average REE-IC was 1522 ± 271 kcal, very close to the result reported by Pinto et al of 1534 ± 300 kcal in a sample of 45 patients waitlisted for liver transplantation, which corroborates the expectation of accuracy of caloric prediction by this method[36].

Comparison of REE-IC values with those calculated by the Harris and Benedict (HB) equation revealed super estimated values. Consistent with other studies[22,34,35], our findings suggest that common predictive equations for estimation of REE could be clinically inaccurate in cirrhotic patients, since they are usually based on body weight, a parameter that can be altered by several factors—such as ascites and fluid retention—and thus directly affect the energy expenditure estimated by the equation[33]. Thus, even considering their low cost and applicability, using predictive equation should consider the aforementioned aspects, since overestimation of REE has been reported in many previously published comparisons[22,34,35]. Corroborating our line of thought, Meng et al[34] found a reduced REE in 53% of their sample of 153 patients with liver cirrhosis.
when measured by IC as compared to REE estimated by the HB equation. Likewise, Teramoto et al[22] evaluated 488 patients and found that the estimated REE was 1256 kcal by IC vs 1279 kcal by the HB formula.  

Boulatta et al[38] aimed to compare the accuracy of seven predictive equations, including the Harris-Benedict and the Mifflin equations, against measured resting energy expenditure (REE) in hospitalized patients, including patients with obesity and critical illness. The authors concluded that no predictive method was accurate when considering accuracy as 90% to 110% of the value obtained by IC. In our study, most of the evaluated predictive methods resulted in an error below 10%. Further, based on our findings, in circumstances where IC is not available, the FAO/WHO/UNU or McArdle et al equations can be used to accurately estimate REE, since they may yield values closer to those of IC in patients with cirrhosis. Also, the IOM equation could be used, since it also showed good agreement in the Bland-Altman analysis, albeit it was significantly different in the t-test. Noteworthy, a previous study including patients with portal hypertension reported that the McArdle et al equation was one of the predictive methods that differed most in REE estimates in the study population[39]. As in our study, IC yielded a higher value than all other methods. The authors noted that all other methods underestimated the predicted REE by more than 200 kcal when compared to IC, except Cunningham’s predictive equation. Therefore, it bears stressing that the same method of assessment in different populations can present different correlations with the available predictive equations.

Although we have not found prior publications supporting the use of BIA to determine REE as a means of extrapolating energy expenditure in patients with cirrhosis, this method was used in a study by Strain et al[40] of morbidly obese patients. There was no significant difference between the value predicted by BIA (which was based on the Harris and Benedict equation) and IC, which could support the indication of BIA as a good predictor of energy expenditure in this population[40]. Our study also found that the BIA equipment was able to predict REE, albeit different BIA
equipment apply different equations to predict REE using body composition parameters, and users should observe which equation is being applied.

We found no significant differences IC between patients classified as Child-Pugh A and those classified as Child-Pugh B. In this respect, our findings corroborate those of Teramoto et al.[22] and Meng et al.[34], who found no statistically significant difference in IC when comparing the three Child-Pugh prognostic classes. Moreover, Belarmino et al.[32] reported that the dietary intake of patients with cirrhosis in their sample was 1.4 times greater than that predicted by IC, while in our study, it was 1.14 times greater. Teramoto et al.[22] found that most patients in their sample had adequate dietary intake and there was no statistically significant difference between Child-Pugh classes, corroborating the findings found in the present study. Meng et al.[34] highlighted that dietary intake can be impaired by factors such as anorexia, weakness, fatigue, low-grade encephalopathy, and restrictions on sodium, protein, and fluid intake. These data in addition to the insufficient energy intake in 48% of the patients studied by Nunes et al.[41], who evaluated a sample of 25 cirrhotic patients and found an average of 2012 ± 720 kcal highlight the importance of adequate estimation of REE in these patients, to prevent malnutrition and improve prognosis and outcomes.

Limitations of the present study include the absence of a healthy control group for comparison and the possibility of recall bias interfering with the 24h dietary recall, despite this being a validated method.

CONCLUSION

The present study aimed to determine the REE of patients with cirrhosis by indirect calorimetry (IC) and compare the values thus obtained to those estimated by bioelectrical impedance analysis (BIA) and common predictive equations. The McArdle and the FAO/WHO/UNU equation showed the best agreement with IC, whilst the IOM and BIA could also be considered appropriate for REE estimation. Further studies in different populations of patients with cirrhosis, including different severity profiles, are needed to determine the best methods for REE estimation in clinical practice.
ARTICLE HIGHLIGHTS

Research background
Patients with cirrhosis commonly present malnutrition, resulting in a significant imbalance in energy metabolism that negatively impacts their prognosis and their quality of life. However, adequate dietary prescription depends on the precision of the protocols for energy requirement estimation, and current literature is still conflicting regarding the relationship between cirrhosis progression and Resting Metabolic Rate (RMR) alterations.

Research motivation
Reliable calculation of resting energy expenditure (REE) in patients with cirrhosis is pivotal to appropriate therapeutic management. However, there is still a need to evaluate which of the predictive equations are more effective in the clinical setting.

Research objectives
The objective of the present study was to determine the REE of patients with cirrhosis by indirect calorimetry (IC) and compare the values thus obtained to those estimated by bioelectrical impedance analysis (BIA) and common predictive equations.

Research methods
This was an observational study performed at the Outpatient Gastroenterology and Liver Transplantation Clinics of Santa Casa de Misericórdia de Porto Alegre, Rio Grande do Sul, Brazil. Data from the electronic medical records of the patients, related to the diagnosis, staging by the Child-Pugh score, age, and sex of the participants were collected. The diagnosis of cirrhosis was made by clinical, laboratory, imaging, and/or, eventually, liver biopsy in accordance with the hospital liver transplant group standards. Bioelectrical impedance analysis (BIA) and Indirect calorimetry (IC) were performed
and the results were compared to energy expenditure predictive equations using the Bland-Altman method, and also the Student’s t-test for paired samples.

**Research results**

Ninety patients, with a mean age of 57.1 years, were assessed. The mean REE measured by IC was 1607.72 and there were no differences comparing groups with different Child-Pugh scores. The IC values were significantly different when compared to predictive methods, except for the McArdle and FAO/WHO/UNU predictive equations.

The best agreement was found between IC and the IOM equation, followed by FAO/WHO/UNU and McArdle equations. The agreement between IC and BIA was below 10% of the mean difference. The Harris and Benedict and the Mifflin equations showed less agreement with the IC values.

**Research conclusions**

The present study determined the REE of patients with cirrhosis, indicating that the McArdle and the FAO/WHO/UNU equation showed the best agreement with IC, whilst the IOM and BIA could also be considered appropriate for REE estimation.

**Research perspectives**

Further studies in different populations of patients with cirrhosis, including different severity profiles, are needed to determine the best methods for REE estimation in clinical practice.
