Thyroid follicular renal cell carcinoma excluding thyroid metastases: a case report and literature review

Sicheng Wu, Xiya Li, Bangjie Liao, kun Xie, Weimin Chen
Abstract

BACKGROUND
Thyroid follicular renal cell carcinoma is a special type of renal cell carcinoma newly recognized in recent years. It has attracted attention because of its unique histology, immunophenotype, and clinical characteristics. It has a very low incidence, and the number of case reports available for review is limited. Moreover, a thyroid mass with type of tumour is rare.

CASE SUMMARY
Here, we have reported a case of a renal mass with a bilateral thyroid mass that was accidentally discovered in a 60-year-old man during physical examination. B-mode ultrasound showed a hypoechoic mass in the middle and lower parenchyma of the right kidney, and computed tomography showed an iso-density shadow tumour in the right kidney. Contrast agents had a significant continuous enhancement effect on the tumour, and the enhancement was not uniform. After partial nephrectomy, pathological analysis was performed to rule out the possibility that the renal tumour was caused by thyroid tumour metastasis. Needle biopsy of the thyroid tumour confirmed that the renal cell carcinoma was not related to the thyroid tumour. The patient was alive at the last postoperative follow-up.

CONCLUSION
This is the third published case in which thyroid tumour biopsy was performed to confirm that TLFRCC is not thyroid related.

Key Words: renal cell carcinoma, thyroid follicular renal cell carcinoma, kidney

Core Tip: this is only the third published report combined with a thyroid tumor biopsy to confirm that thyroid follicular renal cell carcinoma is not thyroid related, and in addition to the typical pathologic features of this tumor, our patient had radiographic features that were different from those previously reported.

INTRODUCTION

Renal cell carcinoma (RCC) is a malignant tumour that originates from the renal parenchymal urothelial system and accounts for approximately 80%-85% of all renal malignant tumours. It is one of the most common tumours in the urinary system, second only to prostate cancer and bladder cancer [1]. Thyroid follicular renal cell carcinoma (TLFRCC) is a rare new subtype of primary renal cell carcinoma that is not a true carcinoma originating from the thyroid gland. Although it is histologically similar to thyroid follicular carcinoma, TLFRCC lacks typical thyroid markers. The rarity of these tumours limits our understanding of them, leading to misdiagnosis and inappropriate treatment. Here, we have reported a case of a 60-year-old man who presented with lower back and abdominal pain. Imaging examination revealed lesions in the right kidney and bilateral thyroid gland. Based on postoperative pathological examination findings, renal metastasis of the thyroid carcinoma was excluded.

CASE PRESENTATION

Chief complaints
A 60-year-old man presented with a >1-month history of distending right lower back and abdominal pain.

History of present illness
A 60-year-old man presented with a >1-month history of distending right lower back and abdominal pain. Computed tomography (CT) revealed small solid nodules under
the capsule in the middle and lower part of the right kidney, leading to the suspicion of small RCC.

*History of past illness*

The patient had a 10-year history of diabetes. He did not take his medicine regularly and had poor blood glucose control.

*Personal and family history*

The patient had no relevant personal or family history.

*Physical examination*

The patient’s vital signs were normal.

*Laboratory examinations*

Admission-related examination revealed a carbohydrate antigen 19-9 Level of 99.98 u/mL and creatinine level of 73.5 umol/L (postoperative creatinine level: 79.1 umol/L). The glomerular filtration rate of the left and right kidneys was 34.88 and 34.89 mL/min, respectively.

*Imaging examinations*

Ultrasound showed a round hypoechoic mass measuring approximately 0.9 × 0.8 cm in the middle and lower parenchyma of the right kidney; however, there was no obvious blood flow signal in the mass. Computed tomography angiography revealed a small nodular iso-density shadow (approximately 1 cm in diameter) in the middle parenchyma of the right kidney that was protruding the edge of the kidney. Enhanced scan showed continuous and obvious enhancement during the arterial phase. However, the enhancement was not uniform, and there were no abnormal tumour-supplying blood vessels (Figure 1). Ultrasound of the thyroid gland performed in our hospital on 5 January 2021 showed bilateral thyroid nodules (TI-RADS3 class).
**FINAL DIAGNOSIS**

Postoperative pathology showed: Macrography, part of the renal tissue, the size of 2.1 × 1.5 × 1.5 cm, had been cut in half in the clinic. Analysis of the tissue section revealed a nodular body measuring 1.2 × 1.0 × 0.6 cm; it was greyish-yellow or greyish white, slightly tough, and had slightly unclear surrounding boundaries. Moreover, it contained of free adipose tissue (5.5 × 3.3 × 1.2 cm) and was not in contact with lymph nodes. Microscopy revealed glandular, cystic follicular, or papillary tumour cells, with uniform size. The cytoplasm was medium stained, lightly stained, or empty bright, and the nucleus was round or slightly irregular with small nucleoli and red-stained lumen. Immunohistochemistry, CK(3+); EMA(+); Vimentin(+); PAX-8(+); CK7(+); Ki67(2%+); P504S(+); E-cd(+); CD117(-); CD10(+); RCC(-); Calponin(-); TTF-1(-); TG(-); TFE3(weak+); S-100(-); WT-1(-); CA9(-). Therefore, TLFRCC of the right kidney was considered (Figure 2).

**TREATMENT**

Laparoscopic partial nephrectomy was performed in December 2020. The patient recovered well after surgery and was discharged after 3 days. Fine-needle biopsy of thyroid nodules was performed in 2021, revealing no obvious pathological abnormality postoperatively.

**OUTCOME AND FOLLOW-UP**

The patient underwent re-examination on 30 March 2021, and the CT showed that the right kidney had changed after partial nephrectomy, but there were no other abnormalities. At the last follow-up, the patient was alive and healthy.

**DISCUSSION**

Previously, TLFRCC was known as thyroid-like follicular carcinoma of the kidney or thyroid follicular carcinoma-like renal tumour, a special type of RCC with thyroid
folicular carcinoma-like histomorphology. This rare, new type of RCC was described in detail at the 2012 ISUP. In 2016, the World Health Organization Classification of Urological Oncology reclassified renal tumour subtypes, and TLFRCC was listed as a ‘tentative renal cell carcinoma’ due to its extremely low incidence rate and small number of cases available for review [2]. This type of tumour was first described by Angell [3] in 1996. Immunohistochemical staining of the reported cases showed positive expression of TG and TTF-1 in tumour cells, although no space-occupying lesions were detected by thyroid examination. However, considering that papillary thyroid carcinoma can develop lymph node or distant metastasis with very small primary foci, we believe that the first case of TLFRCC was reported in an abstract published by Amin [4] in 2004 and in case report published by Jung [5] in 2006. Thus far, approximately 41 cases have been reported [6].

Due to its rarity, the pathogenetic factors of TLFRCC are unclear. Recent studies have found that a previous history of malignant tumour and chemotherapy, especially the use of platinum-based chemotherapy regimen, significantly increased the risk of TLFRCC, but the relationship between the mutual development needs to determined in future studies [7]. Moreover, relevant genetic data on TLFRCC are limited. In only a few groups of genetic tests, there were obvious genetic changes in TLFRCC, but the chromosomal changes were significantly different from each other, and the genetic changes were not consistent with those of other known types of RCC [8]. More cases and studies are needed to find causative factors and genes.

The existing case data suggest that the disease mainly occurs in women. Currently, the youngest reported case pertains to a 10-year-old child [9] in whom the right side was more affected than the left side. The clinical symptoms are not obvious and most lack specificity; they are found accidentally during physical examination. In most symptomatic patients, symptoms manifest as gross haematuria and abdominal pain, while some patients show hypertension [10, 11, 12], repeated urinary stimulation symptoms [12, 13], weight loss [13], and other symptoms. For the preoperative diagnosis of common RCC, CT is the first choice. However, for TLFRCC, preoperative ultrasound
seems to be more accurate than CT in visualizing the mass. On plain CT, cystic-solid changes are usually seen with high-density shadow, clear boundary, haemorrhage, and necrosis. Most of them show weak enhancement on enhanced scan, which is different from the obvious enhancement of other types. Moreover, eggshell-like calcification has been observed around the tumour, while the calcification in other types of RCC generally appears in the tumour centre. However, in our case, plain CT showed a moderate density shadow, while enhanced scan showed continuous obvious uneven enhancement, inhomogeneous enhancement, and no obvious calcification, which was rarely seen in previous case reports. Magnetic resonance imaging generally shows a high signal on T1-weighted imaging and a low signal on T2-weighted imaging compared to the signal in the renal parenchyma. These characteristic imaging findings may have a certain suggestive value for preoperative consideration of TLFRCC; however, pathological and immunological examination need to be performed for diagnosis.

Macrosopically, most of the tumours are clear with false capsule and cystic and solid, with occasional bleeding, necrosis, or cystic degeneration. The section has a medium texture and is greyish white to greyish yellow, which differs from the multi-coloured appearance of clear cell RCC. Microscopically, the most prominent feature of the tumour is the formation of thyroid follicular carcinoma-like structure, and the follicular cavity is filled with red dye colloid-like substance, which is similar to thyroid colloid-like substance. The cytoplasm of the tumour cells is bichromatic or eosinophilic and empty and bright, the nucleus is round and oval, and the heteromorphism is not obvious. Occasionally, the nuclear groove can be seen, the mitotic image is rare, and most of the Fuhrman grades are grade 2. Most cases show positive expression of CK, CK7, vimentin, and EMA; negative expression of the thyroid markers TTF-1 and TG; and low Ki-67 proliferation index. In our case, the tumour was solid, its boundary was unclear, the other histological characteristics were the similar to those previously reported, and the Ki-67 proliferation index was 2%. The malignant degree of the tumour was low, and the postoperative recovery was good.
The pathological diagnosis should be differentiated from thyroid carcinoma with renal metastasis and ovarian Monogerm teratoma with renal metastasis, and the history can not completely exclude the primary TLFRCC. The immunohistochemical markers TTF-1 and TG have important value in differential diagnosis. However, in poorly differentiated or sarcomatoid-differentiated thyroid carcinoma, TG and TTF-1 are absent, which can be distinguished according to whether there is a primary tumour. In addition, attention should be paid to the differentiation with renal thyroidisation [11], other nephrogenic tumours [12], and atrophic kidney [15]. It is not difficult to distinguish them in combination with clinical and histological characteristics. Our patient had bilateral thyroid mass; therefore, we needed to rule out the possibility that the kidney lesion was metastasized by thyroid carcinoma. Thyroid cancer often metastasises to the bone, lung, and liver and rarely to the kidney. There are <30 reported cases of renal metastasis of thyroid cancer origin, and TTF-1 and TG expressions are both positive and strongly positive [16,17]. The specimens of the patient were repeatedly examined by the pathology department of our hospital, and both TTF-1 and TG continued to be absent. Therefore, the possibility of thyroid origin was ruled out, and TLFRCC was presumed to be the primary tumour in the kidney. The diagnosis was then confirmed by thyroid tumour biopsy, similar to the method was used in case reported by Cai [16] and Tretiakova [13].

TLFRCC has a certain degree of invasiveness, could up to T3, and can have retroperitoneal lymph node metastasis and distant metastasis such as skull and meninges [9]. These tumours may metastasise through the blood-derived pathway, but the degree of malignancy is generally low. Surgical resection is the main treatment, which is supplemented by postoperative follow-up. Surgical methods include radical nephrectomy, partial nephrectomy, and resection of the metastatic lesion, which can be performed even if distant metastasis occurs. Except for a few patients with depdifferentiation of sarcomatoid areas [18] or with highly malignant cells [8], there is currently no clear clinicopathological feature that can predict the occurrence of metastasis and its poor outcome. There are limited reports on adjuvant therapy after
surgery,. At present, it is selected according to the general guidelines for RCC, and its unique treatment scheme needs to be actively explored in clinical practice to avoid unnecessary over-treatment and ensure the quality of life of patients. After effective treatment, patients do not easy to relapse, have a good prognosis, and can obtain long-term survival.

**CONCLUSION**

In summary, TLFRCC is a rare subtype of low-grade malignant renal cell carcinoma with certain invasiveness, which usually occurs in young and middle-aged women. Its clinical and imaging manifestations have certain suggestive value, with unique morphological and immunohistochemical characteristics. The diagnosis depends on pathology and immunohistochemistry, and surgical resection is the preferred treatment. The overall prognosis is good, but there is a certain malignant potential, which needs long-term and close follow-up. If the disease progresses, the treatment plan of metastatic RCC should be referred. Due to the low incidence of TLFRCC, there are few studies on it; therefore, further reports are needed to enhance understanding and provide valuable information for its diagnosis and treatment. No recurrence or metastasis was found in our case; however, the further observation is needed in terms of survival time.
